Association with Europe is another matter, and partnership between Britain and France offers many attractions. While the British and French industries are the largest in the free world, with the exception of the United States, and are reasonably complementary in capacity and evenly matched in competence, yet like all the national aircraft industries in Europe their home market is too small. None is strong enough alone to secure a reasonable share of world markets in the face of competition from the United States; even the combined market which Britain and France command might be insufficient to make a solely Anglo-French project economic. The Plowden Committee suggests that the best solution will be found in an association between the British and other European industries jointly to develop and produce as wide a range as possible of aircraft to meet the needs of Europe and sell competitively elsewhere in the world. It recommends that Britain should take the initiative in arranging a conference of European ministers of aviation with the view of formulating a common long-term policy for the manufacture and procurement of aircraft in Europe.

Beyond this the Committee considers that, if Britain is to retain a significant role in the manufacture of civil aircraft, the Government must take a larger share than in the past in financing new projects. Although the British industry cannot expect to win readily from the expanding world market a share large enough to make a major contribution to its own prosperity, it would be a mistake for British manufacturers to opt out of this field of activity. A more stable military programme than in the past will, however, be essential as the basis for the industry's contribution to a future civil aircraft programme. The Committee suggests that the Government should take a greater share of the responsibility for market studies and for formulating new requirements. While it advocates stringent tests before any project is undertaken, it does emphasize the importance of prompt decisions when the facts are known. It also comments that bolder decisions by the Government and manufacturers in the past might have paid dividends for the country. It concludes, however, that it would be undesirable for the Government to instruct the nationalized airlines to buy British or European aircraft exclusively.

The Committee did not examine the efficiency of the aircraft industry in any detail and its chapter on this subject merely suggests some aspects, such as management, which require closer examination. It formed a clear impression that productivity in Britain was not so good as it could be, or as it needs to be if the industry is to be successful. It therefore recommends that the Government should arrange with the industry for a joint full inquiry into its efficiency to determine the weaknesses and to recommend improvements. On the organization of the industry, the Committee was not convinced that existing competition between the new air-frame groups and between the main air-engine groups in the industry was either particularly real or particularly useful. It thought that the future of the defence programme and of international collaboration was at present too uncertain for it to make a firm recommendation on this fundamental point of organization, although all the evidence points to a reduction in the present size of the industry. It considered also that existing relations between Government and the industry had been a great source of frustration in the industry and had hampered the making of decisions and the efficiency of management.

The Committee suggests that what is required in this controversial field is a form of organization which will free the companies from the detailed control, both technical and financial, now exercised by the Ministry of Aviation and which it believes prevents efficient and dynamic management. The new organization would still allow the Government to contribute in varying proportions to civil aircraft projects but would leave the Boards of the air-frame groups to execute these projects without day-to-day control. It should also retain the greatest flexibility possible while the future pattern of the industry is evolving; retaining, for example, the advantage of private enterprise so far as possible, while still recognizing the dominating position of the Government both as provider of finance and as customer. The Government would thus be engaged in the working of the groups and be made directly aware of the consequences to the industry of any Governmental policies on research and development. While it sees no case for public ownership of the aero-engine and equipment companies, it thought that some degree of public ownership of the two main air-frame groups was essential to achieve a framework within which confidence in the future of the industry could be restored.

The Committee considered for this purpose both full ownership, such as nationalization, and a public share-holding. It did not, however, commit itself on this political issue, although it did draw attention to the possibilities of a combination of public and private enterprise. Equally, it did not express any view on the future of the Ministry of Aviation beyond recommending an early survey of the question by the Government. It regarded the question as outside its terms of reference; yet implied criticism of the existing arrangements is easily discernible, and had it been satisfied with the structure or competence of the Ministry of Technology it is difficult to believe that it would not have recommended transfer to that Ministry of whatever functions of the Ministry of Aviation could not widely and appropriately be transferred to the Ministry of Defence. This is fully in line with the comments of the Estimates Committee in its seventh report for the session 1964–65, dealing with electrical and electronic equipment.

The Plowden Committee does, however, add in conclusion a number of comments on the role of Government research establishments which for many years have played an important part in supporting the aircraft industry. These establishments are already engaging in work other than aeronautical, and since the three military projects were cancelled, a limit has been imposed on recruitment with the view of keeping employment at the present level. The Committee does not consider that the basic responsibility of the establishments for research and experimental work in support of the industry needs changing but recommends a shift of emphasis in the kinds of research in their programmes. In future, more emphasis should be placed on research that contributes to the more modest aircraft (especially civil) and weapons which the industry is likely to embark on. It instances the improvement of the aerodynamics of sub-sonic aircraft; the reduction of structural weight by new techniques of construction and new materials; the saving of weight on equipment and systems; improvements in reliability; and the development of more economical methods of construction.

The Committee urges that the specialized knowledge and expertise which establishments derive from their research work should be available to support the industry

in civil projects as needed, but that the establishments should not encroach on or duplicate the project work for which the industry is properly responsible. It also believes it is important that programmes should be kept consistent with the future role of the aircraft industry and recommends strengthening the industrial membership on the Aeronautical Research Council, and overhauling the Council's terms of reference and structure so as to secure a joint Government, industrial and scientific body capable of a more authoritative contribution to formulating the programme of the establishments. It suggests that a reduction over 5 years of 20 per cent in the present annual budget for intramural aerospace research and development would be realistic without detriment to the value and balance of the intramural programme.

In opening the debate on February 1 the Minister of Aviation, Mr. F. Mulley, while welcoming the Report, was distinctly non-committal on controversial issues and merely indicated the Government's views in general terms. When the Government took office the aircraft industry was absorbing a disproportionate share of Britain's resources; the Government accepted the Plowden Committee's general analysis of the situation and intended to help the industry by creating an environment in which the industry could save itself by its own resources. Priority would continue to be given to the policy of collaboration with Europe, but he accepted with reservation the recommendation that for the largest and costliest projects Britain should of necessity buy American. On civil aircraft he agreed that the general financial policy should be one of a 50 : 50 contribution from the Government, and on the size of the industry Mr. Mulley envisaged a specific contraction from the present 250,000 employees to about 200,000 in 1970, largely in the airframe side of the industry.

Mr. Robert Carr questioned the wisdom of being too specific about the reduction but, with few exceptions, criticism of the report and of the Minister's statement was balanced and constructive. Mr. Carr also emphasized the importance of greater continuity of control at every stage of a project, deprecating frequent changes of personnel. He also urged that the Ministries concerned should incorporate into the administrative hierarchy more staff with industrial and technological experience, and closer and more effective association of technical and financial assessments of a project from its conception. Closer formal association of the industry with the Government departments was essential in order to achieve cost effectiveness and there should be greater direct responsibility for execution of a project. More effective incentive contracts must be devised, and, together with some relaxation of security, Mr. Carr suggested stronger Parliamentary control by development of the Select Committee procedure.

Mr. Carr, whose suggestions were welcomed by Mr. Mulley, also strongly supported Anglo-European cooperation, as did later speakers in the debate. Some were critical of the Plowden Committee for its failure to examine more fully questions of efficiency and management, while recognizing the limitations which time placed on the enquiry. Mr. J. Cronin and Mr. N. Atkinson in particular pressed the issue of public ownership, but otherwise the debate was comparatively non-controversial. A welcome feature was the general recognition of the importance of effective association of technical experts in the control of the industry. Sir Ian Orr-Ewing put this particularly well in relation to the Ministry of Aviation, which he thought did not employ on a highly technical job in a scientific sphere enough people of a sufficiently high calibre.

Nevertheless, neither the Plowden Report nor the debate itself throws much fresh light on one of the most critical problems of the aircraft industry and of some other industries—that of accurate estimation of production costs in the face of rapid technological innovation. This is predominantly a problem of management, to which a higher standard of management may in due course be able to contribute to a decisive degree. It is also partly a problem of organization in which the structure of Government is an important factor, and this is one reason for undertaking a new and urgent examination of the place and function, not merely of the Ministry of Aviation, but of other departments concerned with civil research and development. It is also a matter of the effective use of the scientific and technical expert, and of the mechanics of scientific advice, and the Plowden report, like that of the Estimates Committee, could well stimulate the critical and constructive thought on those questions that is now so imperative.

PATENTS AND THEIR PROCEDURE

Patent Protection

The Inventor and his Patent. By Clifford Lees. Pp. x + 334 + 3 plates. (London: Business Publications, Ltd., 1965.) 50*s*. net.

PATENT Protection has been written by a patent agent who has been in practice for some years, with the object of explaining the patent system and its operation to business executives, free-lance inventors and others. With this object in view, the book has been well prepared. It is lucidly written and, indeed, in relation to its rather abstruse subject-matter it is most entertainingly presented, though it is sometimes difficult to be certain what precise audience or reader the author has in mind for some of the chapters.

The extent to which scientists and engineers find themselves involved in patent matters to-day is growing apace. They generally know little about the subject and are content not to know until the necessity arises. They then want to be told what is the right thing to do and to do it.

This book can accordingly be recommended to anyone who finds himself involved in, or concerned with, the subject of patents and wishes to acquire fairly rapidly the requisite background, though in some chapters, for example "Infringement. Opposition and Abuse of Monopoly", the detail is too great for the relatively casual enquirer, and those more knowledgeable would normally consult a more standard reference work.

In order to make the subject-matter more interesting to read and easier to absorb, much of *Patent Protection* has been contrived around a notional private inventor of a new design of potato peeler. In consequence, the practical implication in relation to the applied areas of chemistry and physics, not to mention electronics or electrical engineering, which are most likely to be of concern to the research scientist or engineer to-day, must to some extent be deduced by analogy.

Nevertheless, within the book's compass will be found both the theory and general practice of patent handling with adequate details of the system and procedure in Britain, as well as appropriate references to other such important patent countries as the United States, Germany and France.

The practical side of inventions is not neglected. There are some excellent chapters on practical development, selling and patent licensing. As the author rightly says, "success in this field is relative". It may vary from a modest income for the patentee to the establishment of a

new and flourishing business. It is debatable, however, whether there can be 'success' such as the completion of a prototype which does a job, or the solution of a technical problem, without subsequent manufacture and sale.

There are a few minor comments one might make on the accuracy of some details; for example, the author is inclined to underestimate the total cost of obtaining a United States or overseas patent, but perhaps these are not important in relation to the nature and purpose of this book, which, as the author emphasizes, can in no way stand as a substitute for the advice of the expert.

The book has a good index and some useful appendixes containing lists of libraries where patent specifications are available and of some research organizations who might be able to help or advise inventors.

B. J. A. Bard

A STUDENT'S APPROACH TO METAL JOINING

The Metallurgy of Welding, Brazing and Soldering
By J. F. Lancaster. (Institution of Metallurgists: Modern Metallurgical Texts, No. 3.) Pp. 291. (London: George Allen and Unwin, Ltd., 1965.) 36*s*. net.

WELDING, brazing and soldering are of fundamental importance in modern industry. Not only are they indispensable as constructional techniques, but also the mechanical behaviour of components ranging in scale from transistors to vast engineering structures often depend critically on the quality and design of the joints incorporated in them.

In spite of this, the study of welding metallurgy forms a disproportionately small part of many metallurgy and engineering curricula and there are scarcely any text-books written primarily for metallurgical and engineering students. In the light of this situation, *The Metallurgy of Welding, Brazing and Soldering* fulfils a very real need and Mr. Lancaster has proved a singularly fortunate choice as author. He not only has a broad grasp of the fundamentals of the processes themselves and the welding metallurgy of the different materials he considers, but he also has considerable experience of the different practical problems which may arise. He has made full use of this background to show, wherever possible, the relationship of basic principles and practical implications in a manner which might be copied to advantage by many other authors of engineering and metallurgical texts.

The book starts with a brief introduction to illustrate the historical development of the theory and practice of metal joining techniques. This is followed by a chapter outlining the general characteristics of fusion welding techniques in which the author considers the welding arc, process characteristics, drop detachment, heat flow, reactions in the weld metal, weld pool solidification and the development of residual stress. In the three following chapters fusion welding processes, solid phase welding and brazing, soldering and adhesive joining are considered.

Following chapters deal with the welding of carbon steel, ferritic alloy steels, austenitic and low-alloy steels, and non-ferrous materials, respectively. The treatment is necessarily brief in the space available and the author concentrates on defining the potential metallurgical problems which may arise during welding and showing how they may be avoided through a knowledge of the welding metallurgy.

The two final chapters are concerned with the basic principles involved in welding castings, clad steel and joining dissimilar metals and with a review of the means of controlling quality in welding respectively.

The book is very readable and plentifully illustrated by clear drawings, graphs and diagrams. The quality of the photographs and micrographs, however, leaves something to be desired. No doubt the choice of reproduction process depended largely on the need to keep the price as low as possible but in my opinion a higher quality would have been preferable even at the expense of an extra shilling or two.

Very few of the points made in the book will be seriously disputed but there is one which warrants some comment. Having started Chapter 6 by a refreshingly realistic definition of mild steel (up to 0·3 per cent carbon) the author goes on to say that this ". . . may normally be welded without any preheat or post welding heat treatment". This statement is certainly true for thin plates and sections but is not generally true of thicker plates, especially where the manganese content can approach or exceed 1 per cent.

In conclusion, this book can be thoroughly recommended for use by students embarking on the study of joining processes. However, its usefulness is by no means confined to technical colleges and universities. Practising engineers and metallurgists, even when directly concerned with welding, will find it valuable to have on their bookshelves, as I certainly shall myself.

R. G. Baker

DISLOCATIONS

Dislocations
By Prof. J. Friedel. (International Series of Monographs on Solid State Physics, Vol. 3.) Pp. xxi+491. (London and New York: Pergamon Press, Ltd., 1964.) 120*s*. net.

FRIEDEL has produced an outstanding treatise on *Dislocations* aimed at the research student in physics, in metallurgy and in engineering. That both theory and experiment on dislocations now dominate the study of the physical and mechanical properties of crystals is evident, as this very scholarly treatise ends with a bibliography of twenty-seven close-packed pages, more than a thousand references, most of which have appeared within the past twenty years. There is so much in this book that it is hard to summarize, the only deceptive feature being the relatively slight index. The line diagrams and the photographic illustrations are superb and will be the envy of every text-book writer. The clarity and lucidity of exposition owe much to these.

Elastic theory of dislocations, motions of dislocations, glide, vacancies, interstitials and dislocation climb are all treated in an adequate way, with a minimum of mathematics, but with authoritative thoroughness. The difficult field of imperfect dislocations is clarified by outstandingly lucid line illustrations, beautifully executed and notably clear. In this section twinning and epitaxy are neatly fitted in. The now well-known spiral growth theory, to which Frank has contributed so much, is then briefly summarized, and this completes Part 1.

Part 2, devoted to dislocation networks, deals sympathetically with a formidable subject. In a section on the Frank network, the intriguing subject of crystal whiskers is briefly surveyed, then comes the discussion the metallurgists will have been waiting for, namely, cold working, the relation between dislocations and hardening, annealing, recrystallization, grain boundaries and creep. The scholarship exhibited in these sections arouses admiration. Cleavage and crack propagation are next briefly discussed and here is the one section where I wished that more might have been included, yet this is a purely personal wish and not meant as a criticism.

A shorter third part (96 pp.) deals with interaction of dislocations and other defects such as impurities, precipitates and other crystal lattice perturbations. This section includes a survey of semi-conductors.

In this outstandingly scholarly contribution one aspect which I felt could have justly received more detailed treatment was that dealing with etch pits. But since selection there must be, inevitably some branches must be more lightly treated than they deserve, otherwise bulk becomes impossibly great.

I very much welcome this fine new text on dislocations, despite the fact that there are already perhaps half a dozen or so books on this subject. It is probably the most comprehensive of all and certainly outstandingly lucid in presentation. It will remain a main authority in the field for a long time. S. TOLANSKY

RUSSIAN RADIOPATHOLOGY

Studies in the Pathology of Radiation Disease

By N. A. Krayevskii. Translated by A. Lieberman. English translation edited by Hermann Lisco and Malcolm Walker. Pp. xv+219. (London and New York: Pergamon Press, 1965.) 100*s*. net.

AT first sight it seems pointless to translate a book on the pathology of radiation injury written in 1957 and unamended since. The justification might be that basic descriptions of morbid histology have a permanent value regardless of time, or that there are important Russian data hitherto unknown to the West.

Unhappily in this case neither claim can be upheld. The main bulk of *Studies in the Pathology of Radiation Disease* is an account, tissue by tissue, of the gross and microscopic changes induced by radiation (mostly to the whole body) in dogs, cats and rats. Both acute and chronic radiation effects have been studied using either external irradiation or internally administered isotopes. Many of the descriptions are careful and detailed but the terms used are sometimes vague or undefined. For example, what precisely is meant by "disturbed haemopoiesis . . . in the form of progressive pernicious anaemia"? and, referring to recovery from radiation, "a mobilisation of internal resources occurs which is mediated particularly through the nervous system. Following I. P. Pavlov, we may look on this process as a physiological counter-measure to the disease"?

An extraordinary omission is of any reference to blood platelets. In page after page there are descriptions of haemorrhages in various organs and all are attributed entirely to blood-vessel damage. In fact, the words 'platelet' and 'thrombocytopaenia' do not occur throughout the whole text. In compensation, perhaps, one of the longer chapters (by Prof. Portugalov) concerns the nervous system. His final comment, however, is on the 'slightness' of the radiation effects, and one wonders whether this accords with the general Russian view.

The illustrations are of mixed quality and suffer from a complete absence in the captions of any reference to staining technique or magnification.

It is in the final chapter, "Conclusions", that the lack of modernity is most evident. What is the use of quoting old speculations on radiosensitivity in different phases of cell cycle when the subject has since been studied experimentally? And the references to human radiopathology are inevitably meagre if all that has happened since 1957 is left out. Perhaps a better book could have been written in 1965; certainly this edition cannot be recommended. H. E. M. KAY

THE GRASSHOPPERS AND LOCUSTS OF AFRICA

The African Genera of Acridoidea

By V. M. Dirsh. Pp. xiii+579. (London : Cambridge University Press, 1965. Published for the Anti-Locust Research Centre.) 200*s*. net; 37.50 dollars.

WHAT is the difference between a grasshopper and a locust? The answer will not be found in *The African Genera of Acridoidea*; the reader is expected to know. Indeed, the answer has nothing to do with taxonomy, which is the subject of this book; the distinction is one of ecology and behaviour. In passing, it may be noted that in America they are all called 'grasshoppers': the name 'locust' is reserved for the cicadas. Within the British Commonwealth the grasshoppers follow a more or less 'solitary' existence ; they tend to remain throughout their lives in one locality. But certain species of Acridoidea change their habits from time to time: for long periods they may live solitary lives like the other grasshoppers; but when their numbers increase they reveal a capacity to gather together in great companies or swarms. In this 'gregarious' state they will undertake migrations, the larval stages or 'hoppers' on foot, the winged adults in the air. It is those species with the tendency to enter on such migrations that are called locusts. In certain of these species the gregarious or migratory 'phase' is strikingly different from the solitary non-migrating phase, not only in behaviour but also in coloration, morphology and physiology.

In elementary entomology those Orthoptera with enlarged hind-legs adapted for leaping (the 'Saltatoria' of Latreille) fall into three groups: the long-horned grasshoppers (Tettigoniidae), the short-horned grasshoppers (Acrididae), and the crickets (Gryllidae). Here we are concerned only with the short-horned grasshoppers which are now classified as a superfamily, the Acridoidea, of which the family Acrididae is by far the largest and is indeed subdivided into a great number of subfamilies of which no less than sixteen are represented in Dr. Dirsh's book on the African genera. The vast majority of the species included in these genera would be called 'grasshoppers'. There are only some half-dozen species belonging to the genera *Locusta* and *Locustana* (of the subfamily Acridinae), and *Anacridium*, *Nomadacris*, *Schistocerca* (of the subfamily Cyrtacanthacridinae), which are recognized as gregarious and migratory locusts.

At the present time. most of the major species of plague locusts in Africa and Asia are in a temporary-state of recession. But meanwhile the cultivator is becoming increasingly concerned about the grasshoppers, which in the past had been considered of small importance. When large-scale mechanized crop production was developed in the Anglo-Egyptian Sudan in the 1940's, about a score of local species of grasshoppers became quite serious endemic pests. Species which had normally subsisted on wild grasses found cultivated sorghum an attractive diet, and the cultivation of the soil facilitated their breeding. As mechanized cultivation spreads throughout Africa, the same problems are certain to arise elsewhere. Hence the interest in building up a systematic background to help the entomologist to recognize his potential pests. It may well be that on closer acquaintance some of these grasshopper species will be found to possess latent powers of swarming and migration which will entitle them some day to be called locusts.

The African genera of locusts and grasshoppers as described in this book number about six hundred and fifty and embrace nearly two thousand species. Many of them have been inadequately described in earlier publications. Dr. Dirsh has been faced with a most formidable task in revising, checking and collating all the information (up to 1958) available about these insects and presenting it in a compact but comprehensive form. He has accomplished this task with complete success. Some four hundred and fifty carefully drawn illustrations supplement the descriptions of the genera. There are keys and brief statements of diagnostic characters for families, subfamilies and genera, and a list of the African species in each genus. Geographical distribution is given in general terms. This book, like its companion volume already well known to workers in this field, H. B. Johnston's *Annotated Catalogue of African Grasshoppers*, is published on behalf of the Anti-Locust Research Centre, London. It will be a standard work for many years to come.

V. B. WIGGLESWORTH

MARGARINE—SCIENCE AND TECHNOLOGY

Margarine

Second revised edition. By A. J. C. Andersen and P. N. Williams. Pp. xi+420. (Oxford, London and New York: Pergamon Press, 1965.) 110*s*.

VERY little has been written about the margarine industry despite the fact that it is world-wide and that margarine is a major item in the human diet in many countries. With the first edition of *Margarine* in 1954, Andersen rendered a major service in setting out clearly, and in readable form, the basic principles on which the industry is built.

The present edition, as the preface suggests, retains virtually all the material of the first edition to which has been added the advances of the past decade. Most of the chapters are of a high standard and convey an intimate knowledge of the margarine industry.

The sections on milk and non-fatty ingredients are very comprehensive and indicate clearly the influence which these materials have on shelf-life and market acceptability. This is supplemented by a very useful chapter on storage and preservation which also underlines the importance of good plant hygiene and the correct choice of materials for plant construction.

The chapter on processing is probably the best in the book. The published and particularly the patent, literature has been dealt with in considerable detail, with the result that both chemist and engineer will find much valuable information. The flexibility in equipment and in product properties which is available to the manufacturer is clearly brought out.

A short but valuable section on physical methods of quality control has been added to this edition, signifying that the industry is moving away from the purely subjective assessment of its products.

The chapter on legislation should prove useful to those contemplating exporting or manufacturing outside their own country, although chapters such as this can quickly become out of date.

There is no doubt that this edition will rank as highly as the first. In the past ten to fifteen years the industry has undergone something of a minor revolution. Greater use than ever before is made of a wide variety of raw materials. Advances in refining and processing have improved quality in terms of texture, flavour and keepability to an unprecedented degree. A streamlined flow of crude oils and fats in at one end of the larger factories is coupled with the flow of a range of sophisticated products out at the other end. Although many of the advances are cited separately throughout the book, the total impact, to demonstrate the dynamic state of the industry, would have been greater if they had been reviewed in the introduction. The quality of the photographs also reduces this impact of the book. They are poorly defined and often create an impression of the nineteen-thirties, even though many of them depict quite modern equipment.

There are also a number of points which I feel would have added to the value of the book if they had been treated more fully. Thus, in considering the chemistry of raw materials, organic chemistry is concentrated on at the expense of physical chemistry, yet it is mainly in physical terms that the important qualities of margarine, such as melting and spreading, can be explained.

Any major work on margarine must be incomplete without a considerable discussion on hydrogenation, yet the authors in this case deal with the subject mainly by a limited number of references to other works and a general description of the properties of several hardened fats. Without increasing the size of the book, a little more detail could have been included by reducing the space devoted to some of the historical aspects of margarine manufacture.

Despite the criticisms, I regard this edition as a comprehensive standard text-book on margarine manufacture, which those with either fringe or particular interests could usefully add to their libraries. It is well presented and easily read, and for those seeking greater detail, there is a comprehensive bibliography of papers and patents.

H. Lavery

INSIDE THE BOARDROOM

Investment Proposals and Decisions

By Bruce R. Williams and W. P. Scott. Pp. 100. (London: George Allen and Unwin, Ltd., 1965.) 21*s*. net.

IN 1961 a Centre for Business Research was formed at the University of Manchester as a co-operative venture between the University and a group of business firms who agreed to provide facilities for research into some of the major problems of business. *Investment Proposals and Decisions* is based on studies of the origin and outcome of investment decisions in fourteen of the member firms. The studies were carefully chosen to show in each one capital project where, if possible, investment decisions had been concerned with innovation or expansion and not simply with replacement, involved fairly large expenditure, had been taken some time ago so that the outcome of decisions could be investigated and, finally, were of a kind which involved several departments.

It is not surprising to learn that few of the projects examined conformed to all the requirements. Some could not be studied in isolation while, with others, investigations were circumscribed by the lack of essential documents, key people or sometimes by internal politics. Nevertheless, the studies proceeded, and it is a tribute to the Centre, not only that the investigations have been made, but also that they have been so frankly reported.

The cases described include investment for a new plant embodying a new process for making an existing product; the establishment of a branch factory abroad to remain in front of competitors; the building of a new factory at home to extend a relatively new product range; the introduction of new processes to improve product quality; the wider use of management services and techniques to reduce costs; the introduction of a new product: take-over of another company to acquire a successful product; and, in a number of cases, the introduction of computers for improving data processing. So far as possible, each case is considered against four aspects of an investment decision process—recognition of potential, collection of information, evaluation of the information, and the final decision. From these detailed examinations, Prof. B. R. Williams and W. P. Scott have gleaned some useful findings about the theory and practice of investment decisions and indicate that, although the practice may be based more on 'hunch' than on substantiated principle, the 'hunch' is not necessarily a whim plucked out of thin air. "It may be the result of a subconscious sifting of ideas, information and experience." Some common pattern for investment does emerge, and few aware of boardroom practice will be surprised to learn how, in judging proposals, the status of the sponsor carries great weight. This finding would have emerged in sharper relief if the Centre had found it possible to extend its enquiry to less sophisticated firms where management decisions are arrived at even more intuitively. What matters, however, is that a start has been made and, as a guide for investment decision-making in the future, the book is significant not only for the case studies but even more for its valuable check list for investment proposals. The well-planned structure and succinct writing make for easy reading, and the only detriment in a book which would both enliven and enlighten many board meetings is that the authors seem out of love with indexes.

T. H. Hawkins

The Nuclear Reactor

By Dr. Alan Salmon. (Methuen's Monographs on Physical Subjects.) Pp. 144. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1964.) 16*s*. net.

THE Nuclear Reactor has been produced for honours physics students, postgraduate students of nuclear power and for the non-physicist whose work is associated with nuclear power.

The introductory chapter is followed by chapters covering nuclear fission, the basic theory of neutron behaviour, and the optimum use of fuel and neutron flux flattening. There is a useful chapter on heat transfer, which includes a brief account of the desirable features of reactor coolants. Reactor control and shielding are then considered, followed by a chapter on the reactor as a source of radiation. This includes a description of the basic kinds of research reactors and their characteristics. The final chapter is concerned with future developments, and discusses in some detail the future of nuclear power reactors.

Throughout the book, emphasis is placed on understanding the processes and methods involved. Each chapter has its own set of references and a useful list of suggested further reading. The graphs and drawings are distinct and adequately annotated, and fit well into the text.

For such a compact book the subject of nuclear reactors is soundly treated, though because of its size the book does suffer through its inability to spend enough time on detail. However, the aim of the book—a short succinct account of nuclear reactors—is quite well achieved, and though there are other similar books it should find a welcome place on many bookshelves. V. S. CROCKER

Progress in Medicinal Chemistry

Vol. 4. Edited by G. P. Ellis and G. B. West. Pp. ix+221. (London: Butterworth and Co. (Publishers), Ltd., 1965.) 67*s*. 6*d*.

VOLUME 4 of *Progress in Medicinal Chemistry*, like its predecessors, is a series of review articles. Barnes and Paget, writing on drug toxicity, highlight our remarkable lack of knowledge of the nature of the majority of toxic responses. When so much effort is expended in the production of new drugs, present knowledge of the biochemistry of the toxic response seems disproportionately small. This article merits classification as compulsory reading for all those interested either in the production or in the application of new drugs. The difficult subject of drug receptor interactions is surveyed by Gill with particular emphasis on the shapes of small molecules and on their interaction with proteins. In this rapidly developing field, recent investigations on allosteric enzymes are likely to have a considerable impact. The comprehensive review by Law of recent work on biologically active peptides emphasizes the remarkable progress made during the past ten years. The volume is completed by an article on analgesics (Beckett and Casy) and by one on experimental hypersensitivity (Spencer and West). As might be expected in such a composite volume, the standard achieved varies considerably, but nevertheless there is sufficient thought in some parts of this volume to make it desirable reading. T. S. WORK

Experiments in Plant Hybridization

By G. Mendel. Pp. ix+95. (Edinburgh and London: Oliver and Boyd, Ltd., 1965.) 21*s*.

THIS is a pleasing little volume appropriate both for the Mendel centenary and as a contribution to the memory of Fisher. It contains more than its title suggests, for within its covers we find Fisher's notable essay on the history of science, Fisher's notes on Mendel's paper and Bateson's biography of Mendel, in addition to Bateson's translation of Mendel's paper.

There is little for me to say except to congratulate both editor and publisher. However, a reading of the book prompts a question of some historical interest. Most outstanding science involves not only imaginative ability and painstaking work, but also an element of luck. One remark in Mendel's paper, taken together with Bateson's footnote, suggests an element of luck that has not, so far as I am aware, been noted before. This is that *Pisum* was in fact self-pollinating. Mendel states dogmatically that "It is only in the Leguminosae, like *Pisum*, *Phaseolus* and *Lens*, whose organs of fertilisation are protected by the keel", that numerous varieties maintain "a stability as great as that of species growing in the wild". Bateson comments that "Phaseolus is nevertheless insect fertilised".

Now Vilmorin[1] carried out experiments from 1856–60 with *Lupinus hirsutus* which were not dissimilar to some of Mendel's and based his interpretations on the same dogma that "comme dans beaucoup de légumineuses papilionacées, la fécondation s'y opère généralement à huis-clos et sans l'intervention d'aucun insecte". But one only has to glance at his data with hind-sight to see that he was getting dominant progeny from recessives as well as vice versa, hence that considerable outcrossing was going on.

There may therefore have been an element of luck in Mendel's choice of *Pisum* rather than *Phaseolus* for the bulk of his work. However, though Mendel nowhere throws doubt on the accepted dogma as applied to *Phaseolus*, he designed his experiments with *Pisum* so that he would know if occasional uncontrolled crossing did occur. In other words, though he may have been somewhat lucky in choosing *Pisum*, he would not have been misled had he chosen *Phaseolus*, for though he does not doubt the accepted he made sure it really did apply to his material.

These comments of mine merely illustrate the way in which this book can provoke thought about the factors involved in good experimentation. It should be widely read by biologists and historians of science, and should be in all school libraries. It is not only a document on the foundation of genetics, but a valuable education in the anatomy of experimental science. J. M. THODAY

Administering Research and Development

The Behaviour of Scientists and Engineers in Organizations. By Charles D. Orth, Prof. Joseph C. Bailey and Francis W. Wolek. Pp. x+585. (London: Tavistock Publications, Ltd., 1965.) 50*s*. net.

THE organizational and human problems involved in the management and control of large-scale research and development have received considerable attention during recent years. The most thorough exposition of them in Britain, in relation to Government departments and other bodies financed wholly by the Exchequer, was afforded by the Gibb–Zuckerman report published by H.M.S.O. in 1961. This American book describes the results of a six-year investigation into the behaviour of scientists and engineers employed within industrial research and development establishments. It records case studies conducted in fourteen such establishments covering a wide spectrum of industrial activity, and contains a number of research reports dealing generally with the issues raised by these studies. It includes also a series of so-called conceptional readings which seek to illuminate, from different points of view, the factors affecting behaviour in the environment of research and development work. Perhaps inevitably, a book so composed and on a subject of such complexity is not easily digestible, and the reading and understanding of it would have been assisted had it contained an extraction of a number of common occurrences of general relevance to the situations examined, which could serve as guide-lines for those carrying senior responsibility in the research and development field. WILLIS JACKSON

PREDICTION OF FUTURE LEVELS OF LONG-LIVED FISSION PRODUCTS IN MILK

By B. O. BARTLETT and Dr. R. SCOTT RUSSELL
Agricultural Research Council Radiobiological Laboratory, Wantage, Berkshire

SINCE 1958, when the United Nations Scientific Committee on the Effects of Atomic Radiation[1] made its first comprehensive review of the consequences of world-wide fall-out, many attempts have been made to derive formulae for calculating the level of radioactivity in foodstuffs which is likely to be caused by different patterns of environmental contamination. Information has been obtained mainly by analysing relationships between measurements of fall-out and of dietary contamination made in environmental surveys. Controlled experiments on food-chain mechanisms and information on agricultural practices are, however, important supplementary sources of guidance; besides indicating whether relationships suggested by survey results are causal or fortuitous they can reveal factors which, though unimportant under conditions so far experienced, may require greater consideration in the future. Improved information can be expected as the period during which observations have been made becomes longer because both climatic factors and variations in the seasonal distribution of fall-out influence the transfer of radioactivity to diet. Conclusions previously reached in the United Kingdom[2–4] have, therefore, been reviewed in the light of the more extensive data which are now available.

Consideration has been limited to two nuclides, strontium-90 and caesium-137, in a single foodstuff, milk. These two nuclides are mainly responsible for the internal radiation doses to which long-lived fission products give rise and it is well established that the contamination in milk has provided a good guide not only to the exposure of children but also to that of adults who consume a mixed diet of the type normal in Western countries[5]. Moreover, the data on the contamination of milk are considerably fuller and more reliable than those for other foodstuffs.

The annual average levels of contamination in milk throughout the United Kingdom have alone been considered; predictions for smaller areas or shorter periods would be subject to much greater uncertainty. The country-wide average deposition of strontium-90 used in the present calculations has been derived, from the results of surveys conducted by the United Kingdom Atomic Energy Authority[6–12], by multiplying the mean concentration in rain from all sites for which quarterly determinations were made by the mean rainfall throughout the United Kingdom. The average ratio of caesium-137 : strontium-90 in fall-out is relatively constant, and the deposition of caesium-137 has therefore been calculated from that of strontium-90 taking the ratio of caesium-137 : strontium-90 as 1·7 up to 1961 and 1·5 since then[13]. The country-wide mean levels of radioactivity in milk were taken from the reports of the Agricultural Research Council Radiobiological Laboratory[14–20].

Strontium-90

It has been recognized for many years that strontium-90 may enter milk as a result of both the 'direct' contamination of pastures and other forage crops with airborne debris and the absorption of strontium-90 through plant roots from the soil. The magnitude of these two components is related, respectively, to the recent rate of fall-out and the cumulative deposit in the soil. Equations of the following type have, therefore, been widely used to relate the ratio of strontium-90 to calcium in milk to the rate of fall-out and cumulative deposit of strontium-90:

$$C = p_r F_r + p_d F_d \qquad (1)$$

where C is the 12-month mean ratio of strontium-90 to calcium in milk (pc./g), F_r is the annual deposit of strontium-90 (mc./km²/year), F_d is the cumulative deposit of strontium-90 at the middle of the year (mc./km²), and p_r, p_d are described as the 'rate' and 'soil' proportionality factors. Such equations have been shown to provide a useful basis for predicting both the average levels of contamination in milk in a number of countries and also the world-wide situation[4,5,21]. None the less, the relationship between the pattern of fall-out and the contamination of milk is considerably more complex than the equation suggests. The assumption that the soil factor is constant ignores the progressive penetration of strontium-90 deeper into the soil which will reduce its availability to pasture plants[3]. A further defect is that the equation takes no account of the fact that an appreciable, though variable, fraction of the diet of cattle consists of stored food grown in the previous year; thus the rate of fall-out at that time will influence the extent to which the current diet of cattle has been directly contaminated by airborne debris. In some areas this 'lag' effect of the rate of fall-out may be enhanced due to the absorption by plants of strontium-90 which has lodged in the basal tissues and been retained for several months without being incorporated in the soil.

The inadequacy of equation (1) from this point of view is apparent when the mean annual ratios of strontium-90 to calcium observed in milk throughout the United Kingdom between 1958 and 1964 are compared with those which would have been expected from the measured deposit of fall-out on the basis of the proportionality factors for equation (1), shown in Table 1, which were derived by a least squares analysis of the results of surveys between 1958 and 1961. The average agreement between calculated and observed values was good (Table 2) but for individual years there were appreciable divergences. The calculated values were too low for years when the lag effect was expected to be greatest because of high fall-out in the previous year (that is, 1960, 1963 and 1964); conversely, the calculated values were too high when the rate of deposition had previously been relatively low. An approximately linear relationship was found between the magnitude of these discrepancies and the extent of fall-out in the second half of the previous year. Only a small improvement was obtained when the rate factor in equation (1) was related to the deposition of fall-out in the twelve months ending in June or September instead of to that in the current year. The following equation was, however, found to give a significantly better fit to

Table 1. Estimates of Proportionality Factors for the Transfer of Strontium-90 to Milk in the United Kingdom

	Equation 1	Equation 2
Rate factor (p_r) (pc. ^{90}Sr/g Ca per mc /km²/year)	0 76*	0 70
Lag-rate factor (p_l) (pc. ^{90}Sr/g Ca per mc./km² in second half of previous year)	—	1 13
Soil factor (p_d) (pc. ^{90}Sr/g Ca per mc./km²)	0·19*	0 11

* Calculated from survey data for the period 1958 to 1961 (ref. 28).

Table 2. COMPARISON OF CALCULATED AND OBSERVED LEVELS OF STRONTIUM-90 IN MILK IN THE UNITED KINGDOM

Year	Deposition of strontium-90 (mc./km²)			Strontium-90 in milk			Percentage of strontium-90 in milk attributable to cumulative deposit in soil	
	January to June	July to December	Total	Observed (pc.^{90}Sr/g Ca)	Calculated values as percentage of observed			
					Equation 1	Equation 2	Equation 1	Equation 2
1957	1·6	1·5	3·1	—	—	—	—	—
1958	3·2	2·1	5·3	7·2	91	97	38	22
1959	6·3	1·8	8·1	9·8	104	107	40	23
1960	1·0	0·9	1·9	6·4	92	94	76	44
1961	0·7	1·4	2·1	5·9	107	90	74	53
1962	5·3	5·4	10·7	11·7	119	108	42	28
1963	9·5	9·6	19·1	25·6	90	96	37	21
1964	9·6	5·3	14·9	28·0	82	101	51	25

the data ($P < 0{\cdot}01$), the residual standard error being reduced from 16 to 6 per cent:

$$C = p_r F_r + p_l F_l + p_a F_a \qquad (2)$$

where F_l is the deposit of strontium-90 in the second half of the previous year (mc./km²) and p_l is the 'lag-rate' factor, the other symbols being defined as in equation (1). When the lag-rate factor was related to the deposit in the whole of the previous year, or in the summer months only, a poorer fit was obtained. Proportionality factors for equation (2), derived by least squares analysis, are shown in Table 1. The levels of strontium-90 in milk calculated on this basis agree closely with those observed in each year (Table 2) and it is evident that equation (2) describes the situation in past years more satisfactorily than equation (1).

The introduction of the lag-rate factor leads to a lower value for the soil factor, and a smaller fraction of strontium-90 in milk is thus attributed to absorption from cumulative deposit; it appears from equation (2) that strontium-90 from this source was responsible for from 20 to 50 per cent of the contamination of milk in past years (Table 2). The use of the lower soil factor derived by equation (2) receives some independent support from the fact that a value of 0·14 has been derived from the results of tracer experiments[3] in the United Kingdom in which strontium-89 was distributed in the soil in a manner which is broadly comparable with that observed in surveys of fall-out in permanent pasture in the recent past[19,20].

The adoption of equation (2) causes lower levels of strontium-90 in milk to be predicted when the cumulative deposit is an important source of contamination, the reverse being true when the contribution of the recent deposit, especially that in the second half of the previous year, is large. To illustrate the extent of the difference between predictions based on the two equations, calculations have been made for two hypothetical models of future fall-out, namely: Model A, the rate of fall-out will decrease by a factor of 2 annually. Model B, the rate of fall-out will remain constant. In both models it has been assumed that the annual deposit in the first year is 45 per cent of the cumulative deposit measured at mid-year (that was, the approximate situation in 1963, the year in which the highest levels of fall-out were observed) and that the rate of fall-out was similar in the second half of the previous year. The decrease in the rate of fall-out in Model A is greater than that anticipated in the absence of further weapon trials[13] while the amount of fall-out assumed in Model B would over a few years much exceed that caused by all weapon trials hitherto. Future situations resulting from weapons testing may thus be expected to lie between the two models.

Predictions made by the two equations are compared in Table 3. In considering the situation over long periods it is necessary to take account of loss of strontium-90 from the soil which arises mainly from leaching or from absorption by plants; following the United Nations Scientific Committee on the Effects of Atomic Radiation[5] an average loss of 2 per cent per annum has been assumed.

For the first year the level of contamination in milk predicted by equation (1) is about 20 per cent lower. However, under conditions of decreasing fall-out (Model A) the relative magnitude of predictions based on the two equations changes progressively, the integrated values over 10 and 50 years being about 10 and 40 per cent higher respectively when derived by equation (1). For Model B the two bases of prediction differ to a smaller extent and the difference would be still smaller if an increasing rate of fall-out were assumed.

Caesium-137

Unlike strontium-90, caesium-137 is usually subject to a considerable degree of 'fixation' in the soil on account of its entrapment in the lattice structure of clay minerals and it usually enters plant roots much less readily. It has been suggested that current fall-out is the only significant source of caesium-137 in foodstuffs, but this was disproved in 1960 and 1961. In many countries the decreasing rate of fall-out then caused smaller reductions in the levels of caesium-137 in milk than would have been expected if they were determined solely by the current fall-out[13]. An explanation of the situation seemed to be provided by the fact that caesium-137 can enter plants relatively freely from soils which contain large quantities of organic matter. The surface soil underlying permanent pastures usually shows this characteristic, and experimental investigations have indicated that caesium-137 continues to enter the edible tissues of pastures relatively freely during the 2 years after its deposition[22]. This led to the suggestion that an equation similar to (1) might be applicable except that the soil factor related only to the deposit in the previous two years[23], namely:

$$C = p_r F_r + p_a F_a \qquad (3)$$

where C is the 12-month mean concentration of caesium-137 in milk (mc./km²/year), F_r is the annual deposit of caesium-137 (mc./km²/year), and F_a is the deposit of caesium-137 accumulated over the preceding two years (mc./km²). The values of the proportionality factors (Table 4) were considerably higher than those for strontium-90 because caesium-137 is transferred from the diet of cattle to milk ten or more times as readily as strontium-90 (ref. 24). Levels of caesium-137 in milk between 1960 and 1963 calculated by equation (3) agreed reasonably with those which were observed (Table 5) and it was found that the body-burden of caesium-137 in man could be related to the pattern of fall-out in a similar manner[13,23].

Table 3. COMPARISON OF PREDICTED LEVELS OF CONTAMINATION OF MILK, BASED ON DIFFERENT EQUATIONS, FOR TWO HYPOTHETICAL MODELS OF FALL-OUT

Model	First year	Years 1–10 Integrated value		Years 1–50 Integrated value	
	Both models	*A*	*B*	*A*	*B*
Ratio of strontium-90 to calcium in milk (relative to year 1 calculated by equation 2)					
Based on equation 1	0·8	4·6	12	10	110
2	1·0	4·1	12	7	90
Caesium-137 per l. of milk (relative to year 1 calculated by equation 4)					
Based on equation 3	0·8	1·9	8	1·9	40
4	1·0	2·6	10	3·0	54

Model A, fall-out rate halved each year. Model B, fall-out rate remains constant.

The rate and cumulative total of fall-out in year 1 are taken to be the same in both models, the annual deposit being 45 per cent of the cumulative deposit at mid-year (that is, the relationship in 1963); it is further assumed that the rate was similar in the previous year.

Table 4. Estimates of Proportionality Factors for the Transfer of Caesium-137 to Milk in the United Kingdom

	Equation 3	Equation 4
Rate factor (p_r) (pc. ^{137}Cs/l. per mc./km^2/year)	3·57	3 00
Lag-rate factor (p_l) (pc. ^{137}Cs/l. per mc /km^2 in second half of previous year)	—	6 00
Soil factor (p_d) (pc. ^{137}Cs/l. per mc./km^2)	0 65 (relative to deposit in previous 2 years only)	0 03* (relative to cumulative deposit)

* Unlike the other factors, which are based on the analysis of survey data, the soil factor in equation (4) has been deduced from experimental results.

When, however, the proportionality factors were applied to fall-out data for 1964 the calculated level in milk differed appreciably from that which was observed (Table 5). As the manner in which caesium-137 is initially retained on edible herbage and removed from it by rain differs little from that of strontium-90 (ref. 25), it appeared possible that a lag-rate factor similar to that used for strontium-90 in equation (2) might be applicable. The following equation, which differs from equation (2) only in units used, was therefore applied to the survey data for caesium-137 from 1960 until 1964:

$$C = p_r F_r + p_l F_l + p_d F_d \qquad (4)$$

where C is the 12-month mean concentration of caesium-137 in milk (pc./l.), F_r is the annual deposit of caesium-137 (mc./km^2/year), F_l is the deposit of caesium-137 (mc./km^2) in the last half of the previous year, and F_d is the cumulative deposit of caesium-137 in the soil (mc./km^2). Values for the rate and lag-rate factors derived from survey data by least squares analysis are shown in Table 4; the soil factor appeared to be zero. Calculated values for the mean level of caesium-137 in milk for each year based on these rate and lag-rate factors agreed more closely with those observed than when equation (3) was used (Table 5).

Table 5. Comparison of Calculated and Observed Levels of Caesium-137 in Milk in the United Kingdom

Year	Deposition of caesium-137 (mc./km^2) January to June	July to December	Total	Caesium-137 in milk Observed (pc./l.)	Calculated values as percentage of observed Equation 3	Equation 4
1959	10·7	3·1	13·8	—	—	—
1960	1·7	1·5	3·2	26	98	106
1961	1 2	2·4	3·6	21	116	96
1962	8 0	8 0	16·0	62	100	101
1963	14 3	14·4	28·7	135	86	100
1964	14 3	8 0	22 3	153	71	100

Although the analysis of the survey data provides no evidence that the cumulative deposit of caesium-137 has contributed hitherto to the contamination of milk, experiments with tracer levels of caesium-137 indicate that this nuclide continues to enter the roots of plants, though to a small extent, for many years after its entry into the soil. Thus if equation (4) is to be used for predicting levels of caesium-137 in milk in future situations when the cumulative deposit may exceed the annual rate by much larger factors than has occurred hitherto, it is necessary to consider the possible magnitude of the soil factor. Some basis for so doing is provided by the results of experiments on several British soils; 3–5 years after they had been contaminated the ratio in which caesium-137 and strontium-90 were absorbed by plants was on average only one-fortieth of that in the soil[26]. Using this figure and assuming (*a*) that caesium-137 is transferred from the diet of cattle to milk about ten times as readily as strontium-90 (ref. 24), and (*b*) that the average calcium content in milk is about 1·1 g/l., a soil factor for caesium-137 of about 0·03 can be derived from the value for strontium-90 calculated by equation (2) (Table 1). On this basis, the cumulative deposit of caesium-137 would on average have been expected to account for less than 1 per cent of the caesium-137 which has hitherto entered milk from world-wide fall-out. The analysis of survey results for past years could not be expected to reveal this component and at the present time the soil factor can thus be estimated only from laboratory experiments.

The concentrations of caesium-137 in milk which would be predicted on the basis of equations (3) and (4) are compared in Table 3 for the two models of fall-out which have already been outlined; no allowance has been made for losses of caesium-137 from the soil by processes other than the decay of radioactivity because its movement in soil and absorption by crops are much smaller than those of strontium-90. Integrated over the first 10 years, equation (4) leads to predicted values 20–30 per cent higher than those given by equation (3) for both models; over 50 years under conditions of decreasing fall-out the integrated value given by equation (4) is 50 per cent higher. Over this period the soil would contribute about 20 per cent of the total.

Conclusions

Evidence reviewed in this article indicates that the annual average level of strontium-90 in milk in the United Kingdom is influenced to an appreciable extent by the rate of fall-out in the last half of the previous year as well as by the current rate of fall-out and cumulative deposit. An improved basis for predicting future levels of strontium-90 in milk is therefore provided by an equation which includes a proportionality factor for this 'lag-rate' effect in addition to the rate and soil factors used in former assessments, equation (2). The same type of equation is applicable to caesium-137 (equation 4) though with that nuclide the contribution from the cumulative deposit has been so small that it can be ignored under conditions of fall-out experienced hitherto.

The levels of both nuclides in milk which would be predicted under conditions of fall-out which may be expected during the next decade as a result of weapon testing are not greatly altered when allowance is made for the lag-rate effect. In any year the greatest difference is unlikely to exceed about 20 per cent and averaged over 10 years predictions for strontium-90 would be altered by a smaller amount. This degree of agreement between different methods for prediction encourages confidence in their use to forecast situations over relatively short periods of years; much greater uncertainty besets many other phases of the assessment of the effects of environmental contamination.

If, however, the integrated levels of dietary contamination are considered over long periods, especially when the rate of fall-out is declining steadily, predictions on the new basis diverge substantially from those which were made formerly. Thus, if the rate of fall-out were to decrease by a factor of two annually, the integrated levels of strontium-90 and caesium-137 in milk over 50 years would be expected on the new basis to be respectively 30 per cent lower and rather more than 50 per cent higher than those formerly predicted; this reflects the reduced soil factor for strontium-90 and the small soil factor now deduced for caesium-137. In consequence the ratio of the integrated level of caesium-137 in milk to that of strontium-90 over this period would be twice that previously calculated.

Long-term predictions of this type are subject to particular uncertainties owing to the lack of direct information on the behaviour of nuclides in soil over long periods. None the less, they deserve consideration as they form the basis for estimating the integrated radiation dose, or dose commitment, which will be received by the population; this is regarded as the best available guide to the total impact of radiation from weapon testing[5,13]. The revised proportionality factors suggest that an appreciably larger fraction of the total dose commitment is due to caesium-137 and a smaller fraction to strontium-90 than has hitherto been assumed.

In conclusion it is to be emphasized, first, that although the method of prediction here outlined appears to give a reasonable description of the average situation, appreciable divergences in individual years must be expected

because of climatic variation, and secondly, that the proportionality factors here proposed have been derived for the United Kingdom only. Moreover, variations are to be expected between countries which contrast in climate, soil type and agricultural practices. Thus a recent analysis of relationships for caesium-137 in milk in Sweden[27] gives a rate factor more than three times that calculated for the United Kingdom and a lag-rate factor (which was related to the deposit in the entire previous year) similar to the factor which relates to the deposit during 6 months only in the United Kingdom. Differences, though of lesser magnitude, are apparent between proportionality factors calculated for milk in other countries[5].

ATMOSPHERIC CARBON-14 CONTENT DURING THE PAST THREE MILLENNIA IN RELATION TO TEMPERATURE AND SOLAR ACTIVITY

By Dr. J. R. BRAY

Grasslands Division, Department of Scientific and Industrial Research, Palmerston North, New Zealand

RECENT summaries of temperature, glacial activity and solar activity[1–11] provide more exact climatological patterns than previously available against which to test changes in carbon-14 activity over the past three millennia. These patterns will be used in an attempt to reconcile contradictions in interpretations[12–15] of carbon-14 climate relationships.

Source of data. Data for carbon-14 activity were obtained from numerous investigations in which a radiocarbon date and a historic date were available and in which corrections for deviation in $^{13}C/^{12}C$ ratio had been calculated. Historic dates based on archaeological estimates were not included, but all other dates were accepted. A total of 193 measurements were obtained by these criteria, all but four of which were samples from tree boles dated by ring analysis. Data included thirty-six values from Willis *et al.*[16]; twenty-two values from Suess[17]; nine values from Broecker *et al.*[18]; thirteen values from Damon *et al.*[19,20]; fourteen values from De Vries[12] with A.D. 1840 considered as a base-line with a value of 0·0; eleven values from Münnich[21]; fifty-eight values from Ralph *et al.*[22]; and thirty values from Jansen[23]. Measurements on *Sequoia gigantea* accounted for 139 dates.

The Jansen[23] data included a series on the *Sequoia gigantea* of Willis *et al.*[16] and a series from a previous investigation[24] of *Agathis australis*, which were recalculated by Jansen[23] on the assumption that 150 more annual rings had been burnt off the specimen than had been estimated by dendrologists when the original study was made. Jansen considered this recalculation reasonable since it brought the *Agathis* data in line with trends in the northern hemisphere and since it was unlikely that there were major systematic differences in carbon-14 concentration between the two hemispheres.

The table resulting from the compiled 193 measurements showed a decreasing trend in radiocarbon activity from the earliest included date, about 1200 B.C., to an uneven trough of lower activity from the first to tenth centuries A.D. This was followed by a rise which was especially rapid after A.D. 1300 and which culminated in the fifteenth to seventeenth centuries. A subsequent decline occurred to the mid-nineteenth century, when burning of fossil fuel vitiated results of further measurement. A summation of these results by 200-year intervals (Table 1) showed a decrease from a mean radiocarbon activity of +3·5 per cent in 1203–951 B.C. to a minimum mean value of −0·7 per cent in A.D. 850–1049. This was followed by a rise to a secondary maximum of +1·5 per cent in A.D. 1450–1649, with a subsequent decrease to a mean of +0·5 per cent in 1650–1860.

Carbon-14 and Climate A.D. 1200–1860

Willis *et al.*[16] suggested the most promising line of enquiry into climate–carbon-14 relationships might be to look for evidence of climatic change around the period of rapid increase in carbon-14 activity which their study indicated had occurred during the thirteenth century A.D. (mean carbon-14 activity from Willis *et al.*[16] plus Jansen[23]: 1209 = −0·6, 1259 = +0·2, 1309 = +0·4).

Table 1. Carbon-14 Activity 1203 B.C. to A.D. 1860

Period	*n* Observations	*n* Laboratories	Carbon-14 Mean	Min.	Max.
B.C. 1203–951 B.C.	10	3	+3·1	+1·9	+4·8
950–751	5	3	+2·6	+2·3	+3·0
750–551	6	3	+1·9	+1·4	+2·2
550–351	4	2	+1·3	+0 9	+1·8
350–151	4	2	+0·8	+0·1	+1·7
150–49 A.D.	9	4	+0·1	−0·7	+1·1
A.D. 50–249	7	5	−0·0	−1·0	+1·0
250–449	9	3	−0·0	−1·0	+2·0
450–649	10	3	−0·4	−2·6	+0·4
650–849	16	8	−0·2	−3·0	+1·3
850–1049	18	7	−0·7	−2·3	+1·8
1050–1249	14	8	−0·2	−1·4	+0·9
1250–1449	17	9	+0·7	−0·4	+2·1
1450–1649	26	11	+1·5	−0·4	+3·4
1650–1860	38	11	+0·5	−1·8	+3·5

Mean carbon-14 activity for all data summarized in Table 1 was −0·4 in the thirteenth century and +0·5 in the fourteenth century. This period of rapid increase in carbon-14 activity was contemporaneous with a world-wide trend of declining temperature as indicated by extensive evidence summarized from Greenland[3], Iceland[2,5], Europe[2–4,25,26] and New Zealand[27], which included information on glacial activity and sea-ice, plant growth and distribution, agriculture, mining, and human exploration and settlement.

The appearance of lower temperatures during the thirteenth and fourteenth centuries marked the beginning of a generally cooler period which extended to around the end of the nineteenth century[2,4,5]. During this period, temperatures in England, especially during the summer months, were from 1° to 2° C lower than in the warmer centuries preceding A.D. 1200 (ref. 2), with the interval A.D. 1600–1900 generally cooler than A.D. 1200–1600 (ref. 6). Several intervals of noteworthy low temperatures occurred during the 1300–1900 period. The first was around early to mid-fifteenth century as shown by records of cooler summers in Germany during 1428–1460 (ref. 2), severe winters in France and Germany in the 1430–1440 decade[4] and a recession towards a damper climate near Stockholm in the region of 1450 (ref. 2). The next period of lower temperature occurred towards the end of the sixteenth century as indicated by: (1) resumption of glacial advance in north-west North America at the beginning of the seventeenth century which was dependent on several decades of colder temperature at the close of the sixteenth century[8]; (2) rapid increase of glaciation in west Greenland[7]; (3) complete abandonment of cereal and grain cultivation in Iceland[5]; (4) rapid increase in sea-ice off the coast of Iceland between 1550 and 1570 (refs. 2 and 5); (5) cold winters and wet summers throughout Europe from historic descriptions[3]; (6) abandonment of high alpine mine workings about 1570 (ref. 2). The greatest temperature minimum may have occurred in the late seventeenth century during the latter part of the sunspot dearth period from around 1656–1723 (ref. 8) with especially cold years in the 1690's (refs. 1 and 4) as documented by: (1) historic temperature measurements[2,11] and climatic descriptions[3] in Europe; (2) glacial advance in Europe from 1690–1720 (ref. 11); (3) major glacial expansion in north-west North America from 1700 until 1732 (ref. 9). The early nineteenth century also had cooler temperatures as shown by temperature records[2,11,28] and by glacial advance in north-west North America from about 1811 until 1853 (ref. 9).

The period A.D. 1300–1900 can be summarized as one of generally cooler temperatures and expanding glaciers with parts of the fifteenth, sixteenth, seventeenth and nineteenth centuries especially severe. During this period, carbon-14 activity increased from the minimum levels which characterized A.D. 0–1300 to reach maxima from the fifteenth to the end of the seventeenth centuries. No similar level of maximum carbon-14 activity occurred in the cooler intervals of the nineteenth century, probably because of the increasing release of fossil carbon dioxide.

Carbon-14 and Climate—1200 B.C.–A.D. 1200

Prior to A.D. 1200, there was a milder climate period which extended back to the latter part of the first millennium B.C.[2]. In this period there was little glacial activity and many glaciers which expanded during the A.D. 1500–1900 interval were non-existent or reduced in volume and cover[7,9]. Towards the end of this milder period there was a climatic optimum which occurred around A.D. 950–1200 (refs. 2 and 3) in which there was freedom from sea-ice in the Iceland–Greenland region[2,5], grain cultivation in Iceland[5] and a rise in the altitudinal limits of vineyards in Baden[2]. The long period of lower carbon-14 activity from around the first century B.C. to the thirteenth century A.D. may reflect the milder temperatures which apparently predominated in the middle north latitudes at that time.

The decrease in relative carbon-14 content from around 1200 B.C. to the period of low relative carbon-14 during 100 B.C. to A.D. 1200 may be the result of climatic amelioration following a period of renewed glacial activity. A period of deterioration to a colder climate occurred in Europe in the period 1000–500 B.C.[15], perhaps reaching a climax around 850 B.C.[29]. During this interval there was (1) bog regeneration and (2) increased glaciation in the Alps termed the Larstig and dated by lichenometry as being about 800–500 B.C.[7]. This period was apparently contemporaneous with an episode of glacial advance in Alaska[2].

Carbon-14 and Temperature

The two periods of high carbon-14 activity, 1200–500 B.C. and A.D. 1300–1860, were coincident with the two major periods of lower temperatures and glacial advance since the Hypsithermal. The long period of lower carbon-14 activity from about A.D. 0 to 1200 was coincident with a well-documented period of glacial retreat or stagnation which culminated in the "Little Climatic Optimum". From these long-term trends it seems probable that a lower carbon-14 activity occurred in periods of higher temperature and higher carbon-14 activity in cooler periods. These conclusions support those of Suess[14] and Lamb[15].

An estimate of temperature was made for each century from A.D. 800–1860 based on summaries of temperature[1–6,26,28] and glacial activity[7–9] in Europe and North America. The interval 1600–1860 was divided into solar activity periods as outlined by Bray[9]. The resulting alignment (Table 2) showed a decrease in carbon-14 activity from the estimated minimum temperature intervals in A.D. 1656–1723, 1600–1655 and 1500–1599 to the maximum temperature intervals from A.D. 800–1299. Exclusion of data from the indefinitely dated *Agathis australis* (column 7, Table 2) did not alter the predominant trend.

A comparison was made of radiocarbon activity with mean yearly temperatures conjectured for central England (Table II of Lamb[4]) for the period A.D. 800–1850. Because of the variable amounts of data on radiocarbon activity for the different temporal intervals in Table II, a non-parametric test[30] was applied to these data. This test gave a χ^2 of 4·7 and a probability of $< 0{\cdot}03$, which indicates a significant negative relationship between radiocarbon activity and yearly temperatures in Central England. Analysis of imperfect temperature readings in the London region in the late seventeenth and early eighteenth centuries[1] indicate there was a cool period from around 1688–1702 and a warm period from 1723–1739. Radiocarbon activity was markedly high at the close of the seventeenth century (mean activity = +1·1, 1688–1702), but there are only two values (+0·9, +0·4) from 1723–1739, which are insufficient to determine if a lower activity occurred during this warmer period. The last third of the eighteenth century was notably warm with glacial

Table 2. Variation in Carbon-14 Activity, Temperature and Solar Activity, 800–1860 A.D.

Period A.D.	Estimated temperature	Mean length sunspot cycle (yr.)	Mean yearly sunspot number	Years with sunspots or aurorae (from ref. 33)	Carbon-14 activity n	Mean	Mean‡

‡ *Agathis australis* data excluded.

recession and higher temperatures during 1770–1795 comparable with those from 1925–1950, a period of similar glacial recession[38]. Tree growth over the period 1656–1964 reached a maximum of 9·8 cm²/yr. for *Picea engelmannii* boles in forests in British Columbia, Canada, during the interval 1756–1798 (ref. 9). The next highest growth interval was 1914–1964 with a value of 9·3 cm²/yr. The probable correlation of this growth with temperature[8] gives additional evidence for a warm period in mid- to late-eighteenth century. A maximum tree growth interval in the eighteenth century was also shown for the polar Ural Mountains[31] with a secondary maximum from the 1920's. If the foregoing evidence is considered together with the annual temperature trends for central England[1], a generally cooler period from about 1688–1722 and a generally warmer period from around 1723–1800 can be summarized. The mean carbon-14 activity for the period 1688–1722 was +1·4 compared with −0·1 for the warmer one 1723–1800. This again suggests an inverse relationship between carbon-14 activity and temperature.

The first two decades of the nineteenth century were very cool[1,28] and there was widespread glacial advance in the first half of the century[8,9,28]. Forest tree growth in British Columbia, Canada, for 1799–1833 was 8·7 cm²/yr., a minimum value for the period 1656–1964 (ref. 9). Mean carbon-14 activity for the period 1800–1860 was +0·0, which was slightly higher than the value of −0·6 for the preceding warmer period 1723–1800. Fossil fuel contamination may have appreciably reduced this value, otherwise carbon-14 activity-levels comparable with those in the late seventeenth century might have occurred in the early nineteenth century.

Carbon-14 and Solar Activity

Variation in cosmic-ray flux due to changes in solar activity was suggested as a mechanism for changes in the $^{14}C/^{12}C$ ratio by Suess[17]. Stuiver[32] noted that measurements over the past two sunspot cycles showed a decrease in cosmic-ray flux during sunspot maxima, and he found a similarity between the inverse curve for carbon-14 activity over the past 1300 years of Willis *et al.*[16] and the sunspot activity curve of Schove[10].

Variation in carbon-14 activity in relation to strength of the sunspot maxima per cycle from Schove[10] is shown in Table 3. There is an increase in carbon-14 activity with decreasing strength of sunspot maxima especially at the weaker sunspot maxima levels. Differences in carbon-14 activity between levels were tested with the median test for two samples[30]. The results of these tests showed a significant decrease in carbon-14 activity with increasing solar activity, but the two highest sunspot-levels (106–>136) did not have a significantly lower carbon-14 activity than the two higher intermediate levels (76–105).

Table 3. VARIATION IN CARBON-14 ACTIVITY AND STRENGTH OF SUNSPOT MAXIMA 200 B.C. TO A.D. 1860

Solar activity	Carbon-14 activity	
Sunspot No. for year of maximum*	n	Mean
>136	26	−0·0
106–135	30	−0·1
96–105	15	+0·1
76–95	20	−0·2
66–75	35	+0·4
56–65	17	+1·0
46–55	17	+1·0
<45	5	+1·4

* Data from ref. 10.

Additional demonstration of the tendency for carbon-14 activity to decrease with increasing solar activity is shown in Table 2. The lack of any further decrease in carbon-14 activity at the higher solar activity levels is again apparent. A possible positive correlation of solar activity and terrestrial temperature[8,9] is given indirect support by the interrelationship of these factors with carbon-14 activity.

I thank Dr. E. K. Ralph and Mr. H. S. Jansen for supplying me with copies of their results in advance of publication.

HISTORICAL STUDY OF THE SEASON OF BIRTH IN THE CITY OF YORK, ENGLAND

By URSULA M. COWGILL

Osborn Memorial Laboratory, Yale University, New Haven

AN examination of the contemporary season of birth in man in various parts of the world[1] suggested that a historical study of the matter might reveal some interesting facts. A study of the ten existing parish records of the City of York[2] were considered and one rural parish, namely Gilling[3], which has an excellent record, has also been included. The births recorded in the *Dictionary of National Biography*[4] (*DNB*) covering the period from 1200 to 1900 were also tabulated by hand. This collection was thought to provide good comparative material; though it gives a highly selected body of data, it does not limit its biographical sketches only to those who had attained financial, intellectual and/or religious success. Births were tabulated from *Debrett's Peerage*[5] for the eighteenth and nineteenth centuries and *Who's Who*[6] was used for added material including the latter half of the past century.

All dates before September 2, 1752, were converted to the new-style calendar in order that they should bear a constant relationship to the solar year, since there is evidence[1] from the clear contemporary inversion, seen when Britain is compared with New Zealand, that a basic

cycle determined by the physical progress of the seasons exists. Since, however, the social calendar as well as the meteorological is also probably involved, the position of Christmas as celebrated on the old calendar is indicated by an arrow on the time scales.

The parish records from the City of York largely confine their tabulation to baptism rather than birth. For every half-century a number of births were recorded together with the baptismal date. In the limited number of cases in which data for both events were given, prior to 1750, the average waiting time between birth and baptism is about 3 days. After 1750, with the exception of adults who are being admitted to the Established Church, the waiting time is about 5 days. In most cases the difference is so small that, for the purposes of this study, the baptismal and the birth date can be considered to be essentially the same. While the York data are based entirely on baptismal time the material gathered from the *DNB*, *Debrett's Peerage* and *Who's Who* refers to date of birth.

The tabulated data were normalized for the varying number of days of the month. A monthly mean for the whole year was then obtained and the ratio of the total number of births or baptisms per normalized month to this mean was calculated.

Huntington[7] used the *DNB* data, but with a different end in view, as he hoped to show a difference in the birth seasons of the most eminent, with the longest biographical essays, when compared with those more shortly noticed. This procedure has its dangers, and he perhaps underestimated the *Dictionary* as a compilation of the lives of the extraordinary, rather than necessarily those of political, religious and intellectual leaders. He made no attempt to consider any secular changes in birth season in the data, and his treatment, though worth mentioning, is of no further direct concern to the present study. The same is true of his treatment of Ellis's[8] compilation of one thousand of the most eminent British personalities. It is perhaps desirable to point out that it is not clear how far Huntington normalized his data for varying lengths of the calendar months or corrected for the change from the old style to the new style calendar.

In considering parish records, which are coming to be regarded as major sources of demographic data, Drake[9] has pointed out that the records prior to the eighteenth century are admirable when compared with the eighteenth-century ones, since the latter suffered the effects of a somewhat lackadaisical clergy coupled with the spread of non-conformity. This becomes more apparent when it is observed how long it took some parishes to adjust to the new-style calendar. A problem arises particularly in the seventeenth century, namely that many children died without benefit of baptism, and as such were never included in the record or only under burial headings.

Although it would appear safe to assume that the population of the City of York was not markedly migratory, moving mainly from one parish to another within the city limits, Laslett and Harrison[10] have suggested some caution about such assumptions as a result of their study of Clayworth and Cogenhoe, where an unexpected turnover of population occurred in the seventeenth century. None of these possible sources of error in the records is likely to have an effect on the present demographic study, since they do not seem to introduce seasonal bias. Temporary migrations of labour, regarded by Huntington[7] as of prime importance in determining birth seasons in some communities, are probably of much less importance in an urban population of the kind inhabiting York.

The most striking observation that can be made by examining the season of birth in York (Fig. 1) over the three centuries for which there are data is the initial bimodality, from which it appears that chances for successful conception were equally good in July and January. The pattern then gradually evolved into that now observed where the peak in conceptions occurs early in the summer. After 1752 it appears that an essentially modern pattern has developed.

It is interesting to note that the June minimum in births persists for about the first century for which there are data, gradually shifts to August and finally attains the characteristic November minimum which occurs throughout Europe[1].

The births of people recorded from the *DNB* show, prior to 1700, the same bimodality as that of the York population, with equal chances of conception in the summer and the winter. Prior to 1800, the bimodality is still exhibited by the *DNB* group and the June minimum is still in effect, though the York population shifted to an August one by 1652. The *DNB* people are approaching a modern distribution by 1900 while the York population attained this periodicity by 1752. Somewhat in opposition to a hypothesis proposed by Frazer Roberts[11], where he suggests that winter conceptions are more likely in intelligent families, the people of the *DNB* before 1700 show a slightly higher incidence of babies conceived in the summer than those conceived in the winter. The effect is no doubt somewhat diluted by the recording of the extraordinary that are not intellectually gifted, nor from

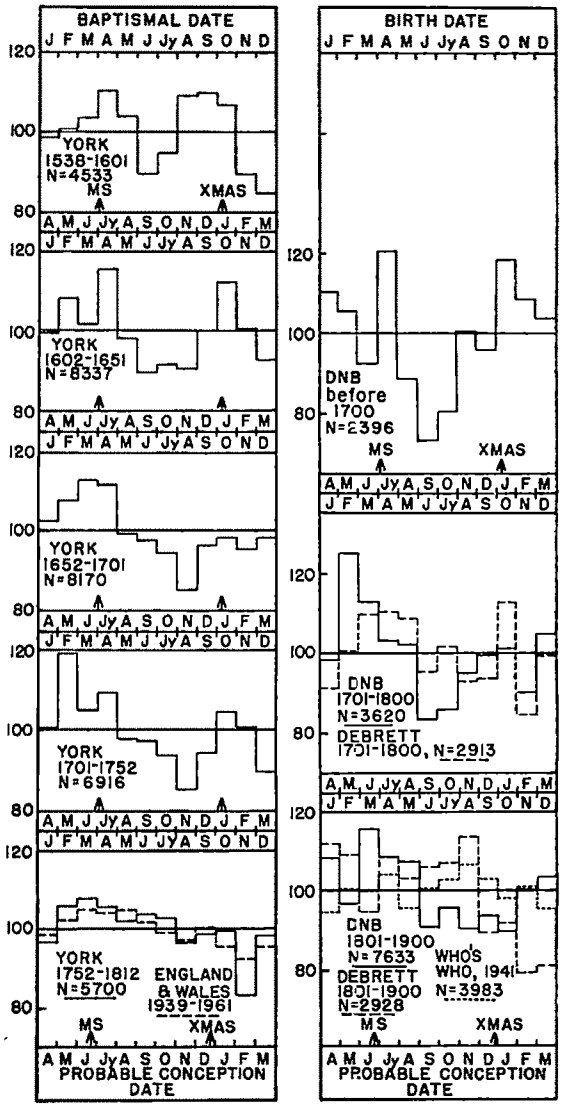

Fig. 1. The season of baptism in York, England, from 1538 to 1812 with the modern histogram of England and Wales (1939–1961) included. The season of birth listed in the *DNB* from 1200 to 1900, those listed in *Debrett's Peerage* in the eighteenth and nineteenth centuries and those in *Who's Who*. The old style dates for Christmas and Midsummer's Day are indicated by arrows. *N* refers to the total number of individuals involved

intellectual families. It is possible, however, that this effect is a modern one. There appears to be an indication in the data from *Who's Who* in which the peak in conceptions is in November.

The peerage for the eighteenth century shows a marked incidence of winter conceptions, though a bimodality is present and the modern November minimum in births is much in evidence. By 1800 the bimodal effect has decreased showing the major peak in conceptions in November with the contemporary November minimum in births. The data, however, are very irregular and no valid conclusions can yet be drawn.

Parenthetically, it may be noted that the sex ratio prior to 1701 in the York population is 104·6 (N = 21,051) while that after this period is 106·9 (N = 12,616) which is about the present English value.

Pasamanick *et al.* have recently shown[12] in a study of a segment of the population of Baltimore that the seasonality, or the amplitude between maximum and minimum, is greater among the poorer classes. The amplitude shown by the population of York is a little over twice as high in the sixteenth century as is now shown for all of England (Table 1). It gradually increases to a peak in the first half of the eighteenth century and then declines somewhat below what it was in the sixteenth century. The *DNB* group shows an extremely high seasonality for all people prior to 1801, at which point it is essentially the same as the York group was for the previous half-century. The peerage shows an increase in seasonality in the nineteenth century which emulates that of the York group during the first half of the eighteenth century. The modern data, both from *Who's Who* and the present material from the British *Census*, indicate essentially the same amplitude in the season of birth. The data are scarcely consistent with the type of effect noted by Pasamanick *et al.* having operated in England throughout the past four centuries. If the dependence of seasonality on economic conditions is due to the more affluent being more protected from the environmental variables by adequate artificial heat and light, the existence of the correlation before the nineteenth century perhaps would not be expected.

Table 1. Seasonality shown by various populations over the period of time studied

Time	*York*	*DNB*	*Debrett*	*Who's Who*	Modern
1538–1601	25·9				
1602–1651	26·1				
1652–1701	27·2				
1702–1751	34·3				
1752–1812	24·2				
Prior to 1700		40·8			
1701–1800		40·4	28·0		
1801–1900		24·6	34·0		
1851–1900				11·0	
1939–1961					11·9

In 1600 the number of baptisms exceeded the number of burials, but from this time onward[13] the number of deaths exceeded the number of births until 1760. After this period the reverse remained true with the exception of data presented for 1780. Many influences were in effect to prevent the natural growth of the population, such as the plague epidemics of 1604 and 1631, the continuous infection of small-pox, measles, influenza and other diseases which brought about one epidemic after another during the early portion of the eighteenth century. Severe weather conditions throughout this time also helped to increase mortality. All such influences may have had a bearing on the well-being of the population and so perhaps on the seasonality. Until further work is done on the matter nothing more can be stated.

The main result of the present investigation is to show that both in the population represented by the York registers and in that from which the *DNB* is drawn there has been a change in the annual incidence of births. Initially there were two major maxima corresponding to maxima in conceptions in July and December or January (N.S.) and minima in September and March. This condition is clearly apparent in York up to 1652 and in the grouped data for the *DNB* before 1700. After this there is a transition, which in York appears to have been completed by the middle of the eighteenth century, to the contemporary pattern with a maximum of conceptions in June, a minimum in November and an extremely small secondary maximum around Christmas. The two original peaks in births, initially of about the same amplitude, thus have become extremely uneven, while the one which has persisted has moved a little earlier into the year. There can be little doubt that the modern pattern is largely meteorologically controlled, as it is well known[1] that it is displaced by six months in the contemporary populations of the southern hemisphere. The most reasonable explanation of the observed historical facts is that superimposed on the climatically determined variation is a cycle of initially great amplitude determined by calendary festivities, notably the celebrations around and after Christmas. This is shown by the seasonal (Fig. 2) distribution of marriages, which in the first period investigated exhibits a dramatic minimum in Lent and dramatic maximum in November, presumably mainly just before Advent. Evidently there was a tradition for being married shortly before Christmas which persists feebly in later half-centuries. The decline in the cycle is, in a general way, historically reasonable. In the medieval period long working days were relieved primarily by religious festivals, which must have set the rhythm of the year almost as much as the physical seasons, to which of course the religious calendar was in effect geared. After the Reformation, and particularly during the times of Puritan ascendancy, the religious calendar became less significant. Celebration of Christmas was in particular anathema to the Puritans, who believed it should be a fast.

Even though it is perhaps straining the evidence to insist that the maximum in Christmas conceptions is lower in the period 1652–1701 than in the subsequent half-century, it is reasonable to suppose the data indicate a gradual break-up of a medieval pattern as the religious practice and secular need for calendary celebrations became less pressing. The physiological and psychological

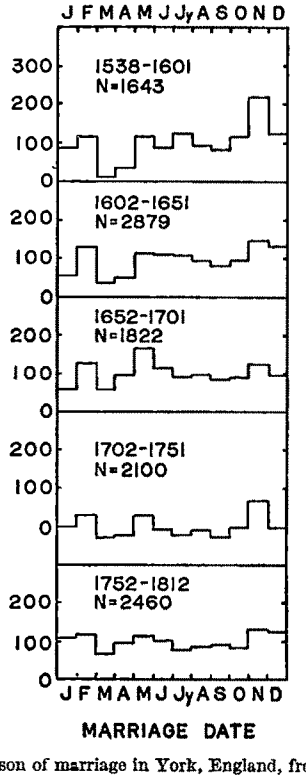

Fig. 2. The season of marriage in York, England, from 1538 to 1812

mechanisms by which the meteorological and social cycles are incorporated into reproductive behaviour remain open questions. It may, however, be pointed out that in the sixteenth century, if the excess of marriages in November resulted in conception within two months of marriage in about 58 per cent of the cases, and live birth, the maximum in births around September would be explained. A good deal of the bimodality, therefore, may be due to customs relating to marriage time combined with a disproportionate significance of primiparous births in a society with a fairly high adult death rate.

The historical aspect of this study was initiated by a grant-in-aid by the Society of the Sigma Xi. Further study was made possible by the generosity of the Wenner-Gren Foundation for Anthropological Research. I thank Prof. G. E. Hutchinson of the Biology Department of Yale University for his continuous support and encouragement.

NEWS and VIEWS

Nuclear Physics Division, Science Research Council : Mr. John Clemow

Mr. John Clemow has been appointed head of the Nuclear Physics Division of the Science Research Council in succession to Dr. A. C. W. Clarke. Mr. Clemow has been a director of G.E.C. (Electronics) since 1961. Previously he was chief engineer (weapons) and a special director of the Vickers-Armstrong (Aircraft) Co., Ltd., Weybridge. Educated at St. John's College, Cambridge, where he read mathematics, Mr. Clemow served with the Royal Artillery and was on the staff of the Military College of Science during the Second World War. He is a Fellow of the Institute of Mathematics and its Applications and a Member of the British Nuclear Energy Society. In 1948 he was seconded to the Royal Aircraft Establishment, Farnborough, and later joined the former Ministry of Supply as director of Guided Weapons Projects.

Applied Mathematics in Monash University : Prof. B. R. Morton

Dr. Morton, senior lecturer in mathematics in the University of Manchester, has been appointed to a chair of applied mathematics in Monash University, Melbourne. Dr. Morton graduated in physics and mathematics in 1948 in the then Auckland University College. He took the mathematical tripos at the University of Cambridge in 1952, and went on to carry out research in fluid mechanics under Dr. G. K. Batchelor and Sir Geoffrey Taylor, qualifying for the Ph.D. degree in 1956. During 1949–50 he was junior lecturer in physics at Auckland University College, and during 1955–56 assistant lecturer in mathematics, University College, London. He joined the University of Manchester as a lecturer in 1956 and became senior lecturer in 1965. In the past few years he has been especially concerned with the organization of postgraduate courses in fluid mechanics at Manchester. Dr. Morton's present research interests are centred mainly on geophysical fluid dynamics and low-speed fluid mechanics. Research projects in which he is at present engaged include: dynamics of rotating fluids, including buoyant jets in a rotating environment and applications to vorticity amplification in the atmosphere, and termination of concentrated vortex cores at boundaries with applications to tornadoes and waterspouts; dynamics of stratified fluids, including motion of vortex parts in a stratified environment and double convection of hot salt systems; flame and fire problems, including turbulent diffusion flames, pool fires, and the ascent of very hot masses of gas; cumulus dynamics, including the development of time-dependent models for growth of cumulus clouds; and a class of pipe flows in which buoyant and centrifugal forces produce important flow rearrangement with interior stagnation and flow reversal. He is a member of a subcommittee of the Meteorological Research Committee of the United Kingdom Ministry of Defence.

Research in Education

In a written answer in the House of Commons on February 15, the Secretary of State for Education and Science, Mr. A. Crosland, stated that the support of the Department for educational research in 1965–66 included about £250,000 for projects related to the schools and schoolchildren, about £55,000 of which would be included in payments to the National Foundation for Educational Research. None of the Department research funds were allocated through the local education authorities, but those authorities, charitable foundations and universities also supported such research.

Directorate of Research and Information

In a written answer in the House of Commons on February 14, the Parliamentary Secretary to the Ministry of Public Building and Works, Mr. J. Boyden, stated that the work of the Directorate of Research and Information included advising on research policy and specific projects, commissioning research work, activities concerned with the dissemination of technical information, and investigation of problems connected with the maintenance of buildings and with the use of computers in the construction industry. The Directorate also dealt with training and education for that industry. The Directorate was headed by a Director, who was a deputy chief scientific officer, and an assistant secretary, supported by twenty-one professional and scientific officers, ten technical, nine executive and twelve clerical officers. The direct cost of the Directorate for 1965–66 was about £165,000, and overheads were estimated at £42,000.

University Building Programme

In a written answer in the House of Commons on February 14, the Secretary of State for Education and Science, Mr. A. Crosland, stated that some 25 per cent of the building programme for universities, including the colleges of advanced technology, for 1965–66 would now be started in 1966–67. The building programme of £120 million for the four years 1966–67 to 1969–70 was not affected by the revised arrangements for dealing with deferment announced by the Chancellor of the Exchequer on February 8.

Man-power in Aviation Research

In a written answer in the House of Commons on February 16, the Minister of Aviation, Mr. F. Mulley, stated that on December 1, 1963, the employees in the scientific officer class in the research establishments controlled by the Ministry numbered 997. For 1964 and 1965 the corresponding figures were 1,022 and 1,037, respectively. The 1965–66 estimates provided £11·75 million for the European Launcher Development Organization.

Morecambe Bay Reservoir Scheme

An alternative proposal to the Morecambe Bay Project is outlined by Prof. J. R. D. Francis and Mr. S. H. Wearne in a memorandum from the Faculty of Technology, University of Manchester. The scheme proposes a marshland reservoir, created by and completely surrounded by embankments on a higher part of the present estuary, the top water-level being about 30 ft. above marsh-level. The reservoir would have a system of aqueducts from rivers and streams and a road link allowing tidal movements into the upper estuary and would thus be permeable. It offers advantages over the barrage scheme in greater depth, outward pressure gradient, lower capital costs and marginally smaller running costs, easier avoidance of waterlogging of nearby land and freedom from obstruction to migrating fish. There are, however, no subsidiary benefits in amenity, cooling water provision or transport links.

Aid to Developing Countries

In a short paper, "Developing Countries in Debt", in the *Westminster Bank Review* for February 1966, Mr. S. E. Mynott points out that besides their continuing need for development finance, the developing countries need measures to enable them to reduce their burden of debt. Taking as developing countries those of Latin America, Africa (except South Africa), non-Communist Asia (excluding Japan) and Oceania (except Australia and New Zealand) and the Mediterranean States of Turkey, Cyprus, Greece, Yugoslavia, Malta and Spain, the total aid given in 1964 is estimated at £2,360 million, net of capital repayments arising from previous aid, more than 80 per cent of which came from the United States (53·5 per cent), France (12·7 per cent), the United Kingdom (7·4 per cent) and West Germany (7 per cent). The total, however, is scarcely increasing even in monetary terms, partly due to difficulties experienced by several donors, such as the United Kingdom, with their balances of payment. Debt servicing is now the main problem for all recipients of aid, and Mr. Mynott discusses the various methods of assistance which could be used. One way is to provide aid on soft terms. Another of more immediate importance is to agree on how debt now maturing can be repaid without excessive strain and without resorting to *ad hoc* arrangements like The Hague and Paris re-finance clubs. Mr. Mynott suggests adoption of the United Nations Conference on Trade and Development experts' liquidity plan.

Employment of Graduates in Biological Subjects

Dr. S. J. Pirt, head of the Department of Microbiology, Queen Elizabeth College, London, writes: "The abstract of information from the University Grants Committee on the numbers of graduates in biological subjects in 1962–63 and their employment (*Nature*, 209, 356; 1966) is a sad reflexion of the paucity of data about the demand and supply of different types of biologist. It does not show the rapid changes which have been occurring in the pattern of demand for biologists. There is no mention of microbiologists, whom it appears are now as much sought after as any other type of biologist. In the U.G.C. data on numbers of graduates for 1962 (*J. Inst. Biol.*, October 1963) we see that there were twenty-eight graduates in microbiology (including bacteriology). Since that time, any increase in the total number would appear to be slight, yet information accumulated in this Department shows that in 1965 more than 140 posts for microbiologists in Britain were advertised. Compare, for example, the zoologists, of whom 170 were available for employment and 138 gained employment. Increasingly one hears complaints from universities and research laboratories that they are forced to work permanently below their establishment for microbiologists. Many of the vacancies in microbiology have to be filled by graduates in some other discipline and who, for many years, at great cost to the progress of their work, learn 'on the job'. This points to another feature veiled by the U.G.C. data, namely, that many biological graduates at the end of their training have to be re-trained in another biological discipline which they could have learned in the first place. Postgraduate training of microbiologists is in an equally parlous state, and this seriously restricts the possibility for growth of university teaching in microbiology. The average number of graduates per year in each school of microbiology is minute (about five). To use staff efficiently, this number should at least be quadrupled. From such a base a steady expansion in the number of graduates could be aimed at which in 10 years might catch up with the demand. Finally, it is interesting to ask, by what means does the U.G.C. propose to avoid a similar dearth of graduates from arising in other rapidly developing sciences ?"

National Museum of Wales

From April 1, 1965, the National Museum of Wales came under the Welsh Office instead of being sponsored by the Treasury. The fifty-eighth annual report of the National Museum of Wales for 1964–65 also records that the great majority of the local authorities in Wales have agreed to contribute to the Council of Museums in Wales (Pp. 91+4 plates. Cardiff: National Museum of Wales, 1965). In the Department of Geology, the compilation of adequate biographies and source-books of Welsh geology (1897–1958) has been completed, while in the Department of Botany the construction of exhibits for the new cryptogamic gallery has continued throughout the year. Two exhibits showing photomicrographs of the anatomy and development of various invertebrates and wild-life conservation were shown in zoology, and in archaeology work was concentrated on the preparation of exhibits for the new Prehistoric Gallery. The new Department of Industry was engaged in the occupation of the galleries and offices allocated, and the Department of Art showed several new exhibitions. In the Welsh Folk Museum work has continued on the re-erection of the tannery removed from Rhayader, Radnorshire. The report also records the usual extensive list of publications by members of the staff.

City Museums and Art Gallery, Leicester

For the year 1964–65, the Museums and Art Gallery of Leicester report a period of consolidation rather than spectacular achievement (Fifty-ninth Report, April 1, 1964–March 31, 1965. Pp. 48+4 plates. Leicester: City of Leicester Museums and Art Gallery, 1965). During the year, the archaeological collections have been removed from the Museum at New Walk to the new Jewry Wall Museum. This has involved transferring many thousands of specimens; some, the tesselated pavements and the Roman milestone, weighing several tons, and almost all, especially the fragile Roman glass, needing great care in handling. Excavations were undertaken north and south of Thornton Lane and a considerable area near the presumed forum was cleared. Labels have been found for the order beds at Belgrave Hall Gardens which promise to be permanent, legible and relatively vandal- and weather-proof. They consist of engraved plastic strips set in metal holders. A list of several hundred accessions

indicates that registration is maintained and is up to date.

Smithsonian Institution

The annual report of the Smithsonian Institution for the year ended June 30, 1964, is, as usual, a large volume and includes several original papers as well as the formal routine reports of the various departments (Pp. xiii + 553 + 71 plates. Washington, D.C.: Government Printing Office, 1965. 4 dollars). During the period under review, the Institution made a determined effort to carry its international activities beyond traditional overseas field expeditions and research, which primarily benefit the Smithsonian, to co-operation with other Government agencies and private institutions in the development of exchange and international exhibits programmes, to the benefit of others. Among the original papers is one in which the computer is brought to bear on Stonehenge from the astronomical angle, and another on recent theories regarding the origin of mountains.

Gems in the Smithsonian Institution

Books and papers on gemstones are numerous, and the Smithsonian Institution has recently issued an excellent handbook to the principal stones in their collections (*Gems in the Smithsonian Institution*. By Paul E. Desautels. Pp. 74. Publication No. 4608. Washington, D.C.: Smithsonian Institution, 1965). An introductory chapter on the characteristics of gems is followed by notes on their shaping, substitutes, lore and a description of the chief gem species illustrated by accurate colour plates. The booklet concludes with a list of the notable gems in the collection at the Institution.

Digital Searching Service for Spectra

The Scientific Documentation Centre, Ltd., has announced a new digital searching service for the identification of unknown substances. The Centre has a library of approximately 64,000 infra-red spectra and about 18,000 ultra-violet spectra. These are coded on eighty-column punched cards. The library can be searched by spectrum (with an accuracy of 0·1μ), by chemical structure, by empirical formula (for carbon, oxygen, nitrogen and sulphur) or, for the less common elements, by elements. Any combination of these methods of search can also be used. The data available consist of spectra from sources in the literature and from eight published spectra collections. These are: American Petroleum Institute Research Project 44, Sadtler Catalogue of Spectra, Sadtler Catalogue of Commercial Spectra, National Research Council–National Bureau of Standards File, Documentation of Molecular Spectroscopy, Coblentz Society Spectra, Manufacturing Chemists Association Spectra and the Infra-red Data Committee of Japan. Computer tapes for infra-red spectra are available for *IBM* 7090, 7094 and 1401, Honeywell 400 and Burroughs 5,000 computers. It is hoped that tapes for *IBM* 7070 and 1460 will be available soon. Further details can be obtained from the Scientific Documentation Centre, Ltd., Halbeath House, Dunfermline, Scotland.

Gallenkamp and Company Ltd.

The name Gallenkamp has for many years past been a household word in the commercial field of scientific laboratory furnishing, equipment, and apparatus; from relatively small beginnings, this firm has grown into an organization of world-wide repute, with headquarters in London, sales and distribution centres at Widnes, Lancashire, and Stockton, Co. Durham, and similar facilities throughout forty-three countries overseas available via appointed agents. Apart from the well-known comprehensive catalogue, occasional leaflets and brochures describing newly designed, specialized instruments and apparatus, Gallenkamp also publish a bi-annual magazine *News and Review* (A. Gallenkamp and Co., Ltd., Technico House, Christopher Street, London, E.C.2. Pp. 24. No. 12, Autumn Issue; October 1965). *News and Review* first appeared as a spring number in February 1960, the motive being then, as simply stated, " . . . we aspired to produce a readable reference to our current affairs", the *raison d'être* of most industrial house-journals to-day. In that first number, the aims of the enterprise were succinctly defined: ". . . the desire to draw attention to apparatus and equipment recently introduced, and to invite enquiries and orders concerning them . . . to further the personal contact between instrument maker and instrument user . . . to pay tribute to those universities, research and industrial laboratories proffering information on the changing methods and new techniques which are constantly being developed . . . news to be offered concerning policy changes, future planning and expansion, price variations . . . news of our Agents (who) look after the interests of overseas customers . . . and other efforts for improving service both at Home and Abroad." These ambitions have been fully realized, so far as the reader is concerned, in the later issues of this publication, and the present number is no exception; it is equally no mere catalogue; much background information on the design, construction, and advantages of modern (often new) apparatus, well illustrated, is included. The introductory article on Magna Carta (1965 was the seven hundred and fiftieth anniversary of its signing) quotes two relevant excerpts; one is of interest to overseas customers: "All merchants are to be safe and secure in leaving and entering England, and in staying and travelling in England, both by land and by water, to buy and sell free all maletotes by the ancient and rightful customs." The other: "Let there be one measure of wine throughout our kingdom, and one measure of ale, and one measure of corn, namely the London quarter, and one width of cloth whether dyed, russet or halberjet, namely two ells within the selvedges. Let it be the same with weights as with measures." This editorial note concludes with the comment: "Was this the first attempt to lay down a British Standard?" For the rest, *News and Review* announces, among many other items, a new orbital incubator, designed in consultation with Dr. S. J. Pirt, Queen Elizabeth College, London; a Mark 2 autoflash Pensky-Martens closed cup flash point apparatus; a new Gallenkamp colorimeter Mark 3, with transistorized stabilizer circuit; a remarkably compact flame analyser, primarily for sodium and potassium determinations (with accessory interference filter for calcium); the Lloyd gas analyser (Gallenkamp hold exclusive licence to manufacture and sell this apparatus); a tube furnace with Crusilite (silicon carbide) elements (manual or auto-control) for temperatures up to 1,400° C; a new international model B-20 high-speed, refrigerated centrifuge; and a well-designed Abbé refractometer with extended range up to R.I.1·740. Available also is the latest development in diamond polishing techniques, 'Microsol', an aerosol application of 'Microfin' diamond polishing compound for metallurgical work.

Fluorocarbon Resins

'Teflon' is the registered trademark of E. I. du Pont de Nemours and Co. for a series of fluorocarbon resins, fibres and films manufactured by them, including polytetrafluoroethylene (PTFE) and fluorinated ethylene propylene (FEB) resins. 'Teflon' was discovered by Du Pont more than twenty-five years ago, and has been available in European markets since the early 1950s. Its unique combination of properties has in recent years benefited an increasing number of industries, particularly in connexion with designing plants demanding material for high-temperature service possessing excellent mechanical, electrical, and chemical properties. An outstanding feature of these 'Teflon' resins is their very high heat

resistance; the PTFE fluorocarbons are capable of continuous service at 260° C (500° F); they can withstand much higher temperatures for limited periods. So important are these 'Teflon' products that they modestly fill a periodical magazine, *The Journal of Teflon*, in their own right, among other Du Pont publications, and a recent issue contains much technical information concerned with their performance in many different circumstances, but notably under high temperature conditions (Du Pont de Nemours International S.A., Case postale, CH-1211 Geneva 24, Switzerland (Du Pont Co. (U.K.), Ltd., Fetter Lane, London, E.C.4). 6, No. 5; October–December 1965).

Among the many successful applications of these resins are: wire insulation rated for continuous service at 260° C; fuel hose in aircraft and missiles at temperatures to 260° C; pump diaphragms rated for service up to 149° C; valve packings handling corrosive chemicals at temperatures as high as 260° C; and ball seals in aircraft valves, to give a leakproof seal at temperatures up to 204° C. It is stated that few, if any, other resins or elastomers can show such an impressive record. In the article describing these properties, information is also given on the behaviour of PTFE resins at temperatures ranging from 149° to 427° C; these should be valuable to the designer in predicting performance and life expectancy of components of these resins at such temperatures. Many of their applications impose severe combinations of mechanical, thermal, environmental, and electrical stresses simultaneously; relevant data for these conditions are given under sub-headings: strength at high temperatures, stiffness and deformation, expansion and friction, electrical properties, special design considerations, and safety in design.

Building in Warm Climates

THE ultimate success of a building should not be gauged solely in terms of its appearance or investment potential; too little consideration is given generally to its functional design. So argues J. F. van Straaten in a paper entitled "Warm Climates and Building" (National Building Research Institute, South African Council for Scientific and Industrial Research, Pretoria. Reprinted from *CIB Bulletin No.* 4, 1964. CSIR ref. *R/BOU* 149. Pp. 5.). The author is chief research officer to the Research Institute, and although his remarks are directed critically to building in warm climates, much of what he says regarding functional design is of much wider significance. Buildings should satisfy minimum requirements in respect of thermal performance, ventilation, lighting, acoustics, structural stability, durability of materials, overall resistance to rain penetration, and all other factors consistent with the functioning of good community and family life. Admittedly some of these requirements are not controlled by climate, but this certainly does play a major part in any concept of functional design. It is claimed that in warm climates, particularly, more research is necessary into effects of asymmetric radiation conditions on sensations of warmth, selection of rational design weather data in terms of probability of concurrence of relevant weather elements, and degree of control of indoor environment by building procedure. Special attention is given in this paper to the thermal performance of heavy-weight and light-weight buildings; it is shown that heavy-weight structures are thermally superior to light-weight structures in warm–arid areas, the opposite applying in warm–humid areas. In considering the thermal environment of buildings, the important factors to take into account are heat-storing capacity of the structure as a whole, insulation properties of the various elements, control of direct and indirect solar heat gains, and rate of ventilation of the building. Some preliminary results of tests now in progress on test structures have so far proved that uninsulated single-skin light-weight construction, even with a concrete floor, is not acceptable for permanent housing; partial insulation of structures serves very little useful purpose; addition of insulation to walls and roof considerably improves indoor living conditions; and if exposed surfaces are painted white, the thermal performance of light-weight structures improved significantly; their ventilation, however, is of prime importance.

Protochordata

THE protochordate section of *The Zoological Record* affords some measure of the sheer enormity of the task of compiling and presenting information of this kind, and particularly so when it is realized that this section is but one of twenty in the present volume of the *Record* (100, section 14; 1963. *Protochordata, together with Pogonophora, Enteropneusta, Graptolithina, Pterobranchia and Phoronidea.* Compiled by Dr. D. B. Carlisle. Pp. 50. London: The Zoological Society of London, 1965. 12*s.* 6*d.*; 1.80 dollars). Section 14 deals with published literature on the Tunicata and Cephalochordata, together with the Hemichordata, Phoronidea and Pogonophora. The information is treated under three headings: a list of titles arranged according to authors; a subject index in which each of the five taxa is dealt with separately; and a systematic index. It is beyond the scope of this review to attempt an evaluation of the entries, but three seem worthy of special mention. The year 1963 saw the publication of Dr. Carlisle's translation of the monograph by Ivanov on the Pogonophora, and in that same year Poulsen recorded pogonophores from the Cambrian of Sweden, thereby giving the phylum a history at least as long as the Phanerozoic Era; in 1963 also, A. H. Müller's text on the Stomochorda appeared. The number of entries concerned with the extinct hemichordate class, the Graptolithina, is impressive, and if the services of a palaeontologist had been enlisted during compilation it is likely that a number of errors would have been avoided. Thus, for example, Llandeilian would not have appeared as 'Llandillian', nor would a reference to *Mesograptus* have been included in the Monograptidae instead of the Diplograptidae. These are minor defects, however, and detract little from the immense value of the publication.

Boarding Schools for Maladjusted Children

THE Department of Education and Science *Building Bulletin* No. 27 is not concerned with the theories of the treatment and cure of maladjustment, and only discusses the personal relationships which play such a large part in therapy where they appear to affect the design of boarding-school buildings (*Boarding Schools for Maladjusted Children.* Pp. v+16. London: H.M.S.O., 1965. 4*s.* net). Its purpose is to analyse the requirements of maladjusted children and to advise the architect on how to produce the sympathetic physical environment which they need. The ideas set out in the *Bulletin* have been assembled in the hope that they may assist local authorities and others concerned with planning new boarding schools for maladjusted children to help the child so that he can return to his normal place in family life as soon as possible. Although the *Bulletin* develops in some detail one particular approach in design, it leaves room for a variety of solutions.

University News: Aberdeen

THE following appointments have been made: *Lectureships*, Dr. P. S. Ashton and Mr. K. Jong (botany); Dr. I. Parsons (geology); *Research Fellowships*, Dr. I. M. Brattsten and Mr. H. Kramer (chemistry).

Belfast

DR. P. W. KENT has been appointed to the chair of biochemistry in the Queen's University of Belfast. The

following lecturers have also been appointed: Dr. M. A. McKervey (organic chemistry); Mr. D. B. McAlister (pure mathematics).

Bristol

The following lecturers have been appointed: Dr. P. Lloyd (physics); Dr. H. E. Rose (mathematics).

Leeds

Dr. J. P. Roberts has been appointed professor of ceramics in the Houldsworth School of Applied Science. Mr. L. T. Hildyard has been appointed lecturer in the Department of Mathematics.

Liverpool

Dr. J. R. Holt has been appointed to the newly established chair of experimental physics. The following lecturers have also been appointed: Mr. T. R. Williams (zoology); Dr. P. A. Chatterton and Mr. B. W. Hogg (electrical engineering and electronics).

Reading

Dr. I. M. Mills has been appointed professor of chemical spectroscopy. The following lecturers have also been appointed: Mr. A. E. Canham (soil science); Dr. C. E. Linderholm (mathematics); Dr. J. R. Milford (meteorology); Mr. H. A. Moisley (geography); Dr. A. P. Musgrave and Mr. G. Rice (applied physical sciences); Miss B. Pickersgill (agricultural botany).

Announcements

Prof. W. Q. Kennedy, professor of geology in the University of Leeds, has been awarded the Clough Medal of the Edinburgh Geological Society for the period 1965–66. Prof. Kennedy has made many important contributions to the understanding of the geology of Scotland in the fields of igneous petrology, tectonics, metamorphism, and Pre-Cambrian stratigraphy.

Dr. H. R. Ambler, who has been scientific adviser to the British High Commissioner in India since 1959, is retiring from his post and leaving India in March 1966. He was chief inspector of military explosives under the Government of India during 1940–47 and director of the Ministry of Supply Tropical Testing Establishment in Nigeria during 1947–54, after which he was assistant director of chemical inspection, Woolwich, before taking up his present post.

Dr. N. Miller, at present James Rowland Angell professor of psychology in Yale University, has been appointed professor of psychology in the Rockefeller University as from July 1.

Mr. H. E. Collins, Mr. L. R. Milligan and Prof. P. R. Owen have been reappointed members of the Safety in Mines Research Advisory Board.

The British and Irish Group for Co-ordinating Human Tumour Investigations, inaugurated in 1963 for the purpose of encouraging the widest experimental investigation of human material, proposes to issue a second bulletin listing and classifying research at present being carried out. Anyone interested in this field of study who wishes to contribute to the *Bulletin* is invited to contact the secretary, Dr. R. W. Baldwin, Cancer Research Department, The University, Nottingham.

The Institute of Biology is arranging a dinner on March 21, 1966, to celebrate the eightieth birthday of Dr. Edward Hindle, founder president of the Institute. Information about the arrangements can be obtained from the Institute of Biology, 41 Queen's Gate, London, S.W.7.

A one-day symposium on "Colour Vision" and "Colour Measurement", arranged by the Colour Group (Great Britain), will be held in the University of Edinburgh on April 1. Further information can be obtained from Mr. R. S. Sinclair, Paisley College of Technology, High Street, Paisley.

A meeting of the Scottish Branch of the Institute of Mathematics and its Applications will be held in Edinburgh on March 18. Prof. E. C. Zeeman will lecture on "A Mathematical Model of the Brain". Further information can be obtained from the Institute of Mathematics and its Applications, c/o the Mathematical Association, Gordon House, 29 Gordon Square, London, W.C.1.

A meeting of the Yorkshire Branch of the Institute of Mathematics and its Applications will be held in the University of Sheffield on March 24. Prof. K. Stewartson will lecture on "The Boundary Layer". Further information can be obtained from the Institute of Mathematics and its Application, c/o the Mathematical Association, Gordon House, 29 Gordon Square, London, W.C.1.

A meeting of the Bristol Branch of the Institute of Mathematics and its Applications will be held in Bristol on March 22. Mr. J. S. Sawyer will lecture on "Mathematics Applied to the Large-scale Dynamics of the Atmosphere". Further information can be obtained from the Institute of Mathematics and its Applications, c/o the Mathematical Association, Gordon House, 22 Gordon Square, London, W.C.1.

MEDICAL EDUCATION IN BRITAIN

THE terms of the Rock Carling Fellowship, which was founded by the Governing Trustees of the Nuffield Provincial Hospitals Trust, provide that the holder shall make a review, by way of a monograph, of one of the fields in which Sir Ernest Rock Carling had been interested. Medical education was one of these, and in the preface to his monograph*, Prof. R. Milnes Walker, emeritus professor of surgery in the University of Bristol, mentioned some of Sir Ernest's activities in this field.

The establishment of a university degree as the only legal qualification to practise medicine was introduced in England as long ago as 1421. During the subsequent centuries, other means of obtaining the right to practise were permitted. For a time, only a minority of doctors held university degrees, and even up to 1938 less than half the medical students obtained degrees; to-day all doctors obtain admission to the Medical Register by a university degree.

The major steps in the evolution of medical education in Britain were the Apothecaries Act of 1815 and the Medical Act of 1858. In the interval between these dates the customary way into medical practice in England was by taking the Membership of the Royal College of Surgeons as a qualification in surgery, and the Licence of the Society of Apothecaries as a qualification in medicine. For those who aspired to Membership of the Royal College of Physicians, for which a university degree was necessary, it was customary to go to Scotland or to the Continent, where a doctorate in medicine was easier to obtain than at Oxford or Cambridge.

The impact of Abraham Flexner's survey of medical education in Europe in 1912 and his further investigation of medical education in general, published in 1925, cannot be exaggerated. It is to be regretted that Britain was so long in heeding his advice.

Many of the recommendations of the Goodenough Committee have now been implemented, however, and they were, in the main, adopted in establishing the relationships between the medical schools and the teaching hospitals when the National Health Service was brought into effect in 1948. Its report made no recommendations about medical man-power but, in an appendix, the Government Actuary estimated that if the number of practising British doctors were to be increased from the then figure of 45,400 to 55,000 in 15 years' time, the medical school entry would have to be raised from the pre-war figure of 1,800 to 2,630. This allowed for a net emigration of only one in every nine doctors. The Committee considered that the increase should be brought about by raising the existing schools to their full capacity before embarking on the establishment of new schools, but it criticized the concentration of medical schools in London and the relatively excessive number of students in the Scottish schools.

Owing to the slow rate of hospital building since the introduction of the National Health Service, the facilities for clinical teaching which the Committee recommended have fallen short of the mark. Their recommendations regarding staffing of pre-clinical and clinical departments have, however, been implemented to a considerable extent. Almost every school now has full-time professors in general medicine and in general surgery, and obstetrics is moving fairly fast in the same direction. Some departments are still deplorably housed and, where this affects pathology and the clinical departments, this has in part been held up by the scarcity of new hospital building. No unit in an undergraduate school in Britain has the control of 100 beds, which was suggested in the Haldane Report as long ago as 1913.

Much progress has been made in implementing the proposal of the Goodenough Committee for the teaching of social medicine, child health and psychiatry, but the maternity training is often unsatisfactory in that students may have to make use of facilities far removed from their teaching hospitals.

The compulsory pre-registration hospital appointments for twelve months were introduced in 1954 and have become an accepted part of the British educational and hospital structure, but the suggested reduction of the undergraduate course to 4·5 years has not come about. That Britain is still short of its needs in medical education has been emphasized in many places, but particularly in the *Review of the Medical Services in Great Britain*, which was published in 1963.

Prof. Milnes Walker referred to some of the changing aspects of medical practice which must influence medical education. In Britain, the increasing average age of the population raises problems as the elderly require an extra share of medical attention. It is wrong to assume that the Welfare State, with its better standards of living, will reduce the demand for medical care. When people have greater means they demand a better standard of medical attention, but they tend to be less inclined to look after their sick relatives at home, and, in fact, conditions often make this quite impossible. So the demand, and the cost, of a National Health Service continue to rise, and as it is unable to meet the demand an increasing number of people take out insurance to cover the cost of private medical attention outside the State Service.

The other important factor is the increased body of medical knowledge, which inevitably leads to increasing specialization. This widens the gap between general practitioners and specialists, and even among specialists themselves. The provision of group practices working from adequately staffed premises would lead to greater efficiency, and provide some means of improving the association between general practitioners and specialists.

Britain is going to be extremely short of doctors. Until recently, there has been one for every 930 of the population, but present figures indicate that there will be a proportion of one to 1,100 in a few years. This figure can be compared with one in about 600 in some European countries, and puts the ratio below that of Australia, Canada and the United States. Doctors are leaving Britain permanently at the rate of 400 a year, and this figure may well rise unless conditions in the Health Service are radically altered. It is important that enough doctors be trained for home needs and for emigration. An annual intake into medical education of about 3,500, which is almost a 50 per cent increase on the present number, should be the ideal.

In discussing courses and syllabuses, Prof. Milnes Walker advises the abolition of the First M.B. examinations; the medical schools would cease to teach the pre-medical subjects in their present form to medical students.

The pre-clinical course should be increased to 2·5 years, or 3 years if a science degree is taken, but provided there was a second year of pre-registration appointments, the clinical period could be reduced to 2 years.

**Medical Education in Britain.* Pp. 101. (London: The Nuffield Provincial Hospitals Trust, 1965.) 5*s*.

Of the 2 years of compulsory pre-registration appointments, the second year need not be one of residence in hospital, and, for many students, part of it should be spent in general practice, approved for the purpose and working from a health centre.

The aim should be to increase the intake of medical students to 3,500 a year as quickly as possible. Pre-clinical schools could be expanded to an intake of up to 200, but clinical schools should not normally have an intake of more than 100. Thus, more clinical schools would be required, and at present there are suitable hospitals in some of our provincial cities with medical schools which could be adapted as second clinical schools without great expense, and would share the university departments. The number of pre-clinical schools in London could thus be reduced.

In teaching hospitals the distinction between general medical and surgical wards should be abolished, but the teams in charge would comprise both physicians and surgeons, and the leaders of the teams might belong to either discipline.

In postgraduate training the increase in the organized teaching in district hospitals is welcome, and will need further expansion if a second pre-registration year is introduced. In London another look should be taken at the grouping of the special hospitals and institutes and some of them might be associated with or even incorporated in general hospitals.

For the better organization of postgraduate training of overseas doctors, an increase in the contacts with these countries and their medical schools is desirable, and regional boards might play a part in this.

SYMMETRY PRINCIPLES AT HIGH ENERGY

IN so rapidly developing a subject as elementary particle physics frequent conferences play an important part in the exchange of knowledge. The doyen of such meetings is the 'Rochester' Conference, affectionately called after its place of origin even though to-day its meetings are as likely to be held in Geneva or Dubna. It is a gathering of several hundred theorists and experimenters, and when it comes together every two years its sessions are concerned with all aspects of the subject. A necessary complement to so large and infrequent an assembly is the holding of regular small conferences on specific topics. The Coral Gables Conferences on Symmetry Principles, organized by the Center for Theoretical Studies of the University of Miami, have come to occupy an honourable place among such meetings.

The first two Conferences were held during a hectic and euphoric time for the practitioners of symmetry principles: the rapid discovery by experimentalists of more and more particles was matched by the invention by theorists of higher and higher symmetries with more extensive multiplets in which to locate them. Such boom conditions could not last for ever and if the atmosphere at the third Conference in January 1966 was less feverish this simply reflected a return to normal after the heady days of the immediate past. There were, nevertheless, many contributions of sober interest.

One of the most powerful techniques in symmetry physics has been the use of the current algebras invented several years ago by Gell-Mann and exploited by him to give many results in agreement with experiment. The method takes as its basic assumption the equal-time commutation relations of the integrated components of certain currents associated with weak, electromagnetic, and (by means of another assumption called the partially conserved axial current) strong interactions. During the past year Fubini and Furlan devised an important way of using dispersion theory in these calculations and this was employed by Adler and Weisberger to calculate the ratio of the Fermi coupling to Gamow–Teller coupling in β-decay, in excellent agreement with experiment. However, a useful assumption in many calculations, namely, that the commutation relations are saturated by a small number of neighbouring states, encountered certain theoretical difficulties which were pointed out by Coleman. In his address to the Conference, Gell-Mann explained how these difficulties could be avoided by working with matrix elements of states corresponding to infinite momentum and using only that sub-algebra of currents which has finite matrix elements to states of finite mass in this limit. It is known that the octet and decimet baryons of $SU(3)$ do not saturate these relations. Gell-Mann and Dashen are engaged on a calculation using various low-energy experimentally determined parameters as the input by which they hope to determine what further states are needed for saturation and so to arrive at a prediction of the nature of the higher-lying baryon resonances.

The current algebra technique does not commit its users to the belief that the algebra involved is a symmetry of the Hamiltonian applying to the whole of physics. It is only necessarily relevant for the matrix elements of the particular currents involved. Current algebras are thus essentially statements about the dynamical workings of the theory rather than about general invariance requirements. The relation between broken symmetries and dynamics is one that is little understood. Many people believe that the answer lies in a bootstrap theory which pictures elementary particles as all being bound states of each other, held together by forces due to the exchange of the particles themselves. In this way no particle is more elementary than any other and they can all be regarded as being composite. Simple models suggest that such theories might lead to symmetries, and Capps presented a contribution at the Conference on this question. However, realistic dynamical calculations are extremely difficult, not least because of a lack of understanding of the effect of multiparticle states on the structure of the theory.

The second Coral Gables Conference had heralded the entry of non-compact groups into elementary particle physics by the construction of relativistic versions of $SU(6)$. The unitary representations of these groups, which are needed in quantum mechanics, are infinite-dimensional and considerable ingenuity was expended in breaking the symmetry in elegant ways so that finite multiplets corresponding to sets of elementary particles could be obtained. However, ever since hole theory, elementary particle physicists have enjoyed making a virtue of vice, so that increasing numbers of people have thought that the presumably infinite sets of all elementary bosons and fermions, discovered and yet to come, might correspond to two or more infinite-dimensional representations of a non-compact group. This idea of killing infinitely many birds with one stone gained some encouragement from the fact which had long been known that the bound states of the hydrogen atom correspond to a single representation of $O(4,1)$. Fronsdal and Rühl gave details of some investigations they had made along these lines. Some initial difficulties in the satisfactory coupling of representations have been overcome and an unexpected feature is that the Born approximation already gives non-trivial momentum-dependent form factors. Another worker in this field is Salam, and his absence from the Conference owing to illness was much regretted both for

this reason and for the fact that his enthusiasm for symmetry physics is one of the expected pleasures of such occasions.

Non-compact groups are the mathematically opulent approach to elementary particles. A more mathematically economical, if physically rather opaque, line of attack is afforded by the use of quark models. Indeed, so economical is this latter approach that it has been noticeably successful in getting many of the $SU(6)$ results without actually assuming $SU(6)$. An investigation of this was reported by Lipkin. Characteristically he finds an interesting new sub-group as the cause.

An elusive particle (if it exists at all) is the magnetic monopole suggested by Dirac in 1931. As he pointed out, it is theoretically desirable since it leads to the otherwise unexplained quantization of electric charge. Schwinger gave a new account of the theory which leads to a different, more restrictive, quantization condition.

The final arbiters of all symmetry schemes are the experimentalists, whose findings can sometimes confirm and often destroy a theoretically elegant possibility. Excellent surveys of the present situation were given by Samios and Frisch. However, occasionally the theorists can get their revenge. Another experimentalist gave a talk on an experiment which he was planning, but a very quick-witted theorist pointed out in a spontaneous comment that the effect sought was identical with, and thus not capable of being disentangled from, another interaction also present. As someone else pointed out, the saving as a result of this observation more than paid for the whole Conference.

J. C. POLKINGHORNE

EARTHING OF ELECTRICAL SYSTEMS

THE safety and integrity of electrical power supply systems are almost universally dependent on some form of earthing which aims at limiting, under fault conditions, the potential difference between the general body of earth and certain parts of the system. The British Standards Institution has recently published a Code of Practice (*CP* 1013: 1965—*Earthing*) dealing with the subject*.

System earthing, as distinct from the earthing of electrical apparatus, began in the 1890's when the supply was utilized almost wholly for lighting and the need for equipment earthing on consumers' premises was relatively slight. Practice in the matter of earthing consumers' installations developed relatively slowly. While there is no mention of earthing in the first edition of the Institution of Electrical Engineer's *Wiring Regulations* issued in 1885, the third edition of 1897 recommends the earthing of the frames of dynamos and motors and of transformers. The eighth edition published in 1924 contains a substantial section dealing with consumers' installations and mentioning the provision of earth terminals.

Although the safety of electrical installations is a subject which has received much attention in recent years, it is probably not generally sufficiently realized that satisfactory protection by means of simple earthing, together with fuses or circuit breakers, becomes progressively more difficult of achievement as the load taken by the consumer increases.

While, in general, the question of how an electrical system shall be earthed is governed by legislation, the regulations are so worded as to permit any type of earthing provided that it is as safe as is practicable and that it is unlikely to interfere with telecommunication.

The new code of practice deals comprehensively with general considerations and with specific practices relating to the earthing of supply systems and of consumers' installations. There are six main sections, two of which, entitled "General" and "Design Considerations", deal with principles and practice concerning power stations, transmission and distribution systems, consumers' premises, traction and lightning protection. Sections 3, 4 and 5 deal respectively with the temporary safety earthing of high-voltage apparatus or mains, inspection and testing and maintenance. Section 6, which completes the work and is entitled "Miscellaneous", is concerned mainly with a number of specific legislative provisions.

Opening with a statement of scope, followed by a list of definitions, the subject is developed clearly and concisely and with an adequate amount of explanatory material. The Code constitutes an admirably comprehensive guide to earthing practice which will be a work of day-to-day reference for supply engineers, electrical contractors, maintenance engineers and, indeed, for all who have responsibility for electrical installations.

VOLCANOLOGY RESEARCH IN NEW ZEALAND

IN 1963, the Royal Society of New Zealand and the New Zealand Geological Survey (Department of Scientific and Industrial Research) invited the International Association of Volcanology to hold its 1965 symposium in New Zealand, to mark the centenary of the New Zealand Geological Survey. This symposium, held during November 22–December 3 at Auckland, Rotorua, Taupo and Wellington, was attended by more than one hundred delegates from twenty-three countries. The two main subjects were acid volcanism (including ignimbrites) and geothermal resources.

The problem of the genesis of acid volcanic rocks is particularly acute in an area such as the central volcanic zone of the North Island of New Zealand, where the volume of these highly silicic rocks greatly exceeds that of basic and intermediate types, and where individual eruptive units of acid rock are of such enormous volume. The problem hinges on whether this acid magma was produced by the large-scale fusion of crustal material or is a fractionation product of basic magma, itself generated originally within the upper mantle. A further possibility is that the acid magma may even come directly from the mantle.

In New Zealand, the basement which is believed to underlie the volcanic rocks includes a great thickness of Mesozoic to Tertiary greywackes. The chemical composition of these greywackes is such that their partial fusion could produce a melt similar in composition to the observed acid volcanic rocks. This origin is at present favoured by New Zealand geologists; basic and intermediate volcanic material is not sufficiently abundant to be quantitatively acceptable as a parental magma. Geochemical studies which have a bearing on this problem were discussed

during the symposium from other circum-Pacific areas, and it was shown how the $^{87}Sr/^{86}Sr$ and $^{18}O/^{16}O$ ratios supported the concept of crustal fusion for the origin of certain extensive acid volcanic accumulations in Guatemala.

It is now known that in volcanic fields such as the central zone of New Zealand, where acid volcanic rocks are present in enormous bulk, a high proportion of the acid material was ejected in fragmental condition by great explosive eruptions. The resulting pyroclastic sheets have a total volume in the Taupo–Rotorua district of New Zealand of the order of 20,000 km³. Particularly noteworthy are the deposits called ignimbrite ('shower-of-fire rock') by the New Zealand geologist, Marshall, in 1935. These deposits are the products of glowing cloud-type eruptions several orders of magnitude greater than has ever been observed in historic eruptions. Often the disrupted particles of magma were still so hot when they came to rest, even at a distance of several tens of kilometres from the vent, as to weld together. Similar deposits have since been found to be widespread in many parts of the world, and the term 'ignimbrite' is now internationally used (although its usage has been varyingly interpreted).

Outstanding contributions to the understanding of the nature and origin of ignimbrites have in recent years come from Japan, New Zealand and the United States, and the recent findings were discussed at the symposium. The relationship of many of these ignimbrites to large collapse calderas, about which they are distributed, is particularly striking; the formation of these calderas seems to be consequent on the rapid emission of huge quantities of fragmented rhyolitic magma.

The central volcanic zone of New Zealand, wherein virtually all the active volcanoes lie, includes, at either end, large andesitic volcanoes—Ruapehu, Ngauruhoe, Tongariro and White Island—which are quite frequently in eruption, although they seldom produce large volumes of new rock. In contrast, the central part of the zone, which includes Lakes Taupo and Rotorua, is characterized by occasional rhyolitic eruptions of extreme magnitude, and the geological record indicates that such eruptions recur at intervals of the order of several thousand years. In this connexion, the problem of the definition of 'active volcano' is particularly pertinent; although the last great eruption was nearly 2,000 years ago, the Taupo–Rotorua area must be regarded as one of high volcanic potential.

To offset the volcanic risk, New Zealand is fortunate in having geothermal fields of great economic value in the central volcanic zone. Since 1952 a power station has been producing more than 100 MW of electrical power from natural steam tapped by boreholes at Wairakei. Drilling programmes in other parts of the zone are at present investigating the further exploitation of this natural asset. Scientific papers presented during the symposium discussed such problems as the economic extraction of the geothermal energy, and theoretical aspects, such as the manner of transfer of heat within a geothermal system. Data were presented from geothermal fields in Iceland, Italy, Japan and the United States as well as from New Zealand.

New Zealand, a leader in the field of geothermal power, was among the first to take steps in the harnessing of the great energy output of volcanoes. Many nations are now following this lead.

G. P. L. Walker

RESONANT SPIN STATES IN THE SOLAR SYSTEM

By PETER GOLDREICH and STANTON J. PEALE
Department of Astronomy and Institute of Geophysics and Planetary Physics, University of California, Los Angeles

TWO explanations have recently been proposed to account for non-synchronous rotation of Mercury[1]. In the first, Peale and Gold[2] showed that the vanishing of the time-averaged tidal torque on Mercury would imply a rotation rate which is intermediate between the planet's instantaneous orbital angular velocity at perihelion and its mean orbital angular velocity. The asymptotic spin angular velocity is determined by the amplitude and frequency dependence of the planet's 'Q' ($1/Q$ is the specific dissipation function[3]). For some reasonable Q's the final spin rate is near the observed 59 days. More recently, Colombo[4] has proposed that the rotation period of Mercury may be precisely 2/3 of its orbital period of 58·65 days. He suggested that this commensurate rotation rate might be stable if the figure of Mercury possessed a sufficiently large permanent deformation from axial symmetry with the long axis oriented toward the Sun at perihelion. Our investigation of such commensurate spin rates indicates that Mercury may indeed have a stable spin velocity which is 3/2 the orbital angular velocity but in one sense almost despite its permanent deformation rather than because of it.

We consider a planet the spin axis of which is normal to its orbital plane. The principal moments of inertia of the planet are denoted by A, B, and C; C being the moment about the spin axis, and B and A being the larger and smaller of the moments in the equatorial plane. The planet moves in an orbit with semi-major axis a, eccentricity e and instantaneous radius r. In Fig. 1 we illustrate the angles we shall use. Line IF is fixed in inertial space, whereas line PS is the planet–Sun centre line. The angle between the long axis of the planet and the centre line is Ψ, f is the true anomaly and θ gives the angular position of the long axis relative to the inertial line IF. In the absence of tidal torques the equation of motion for θ is (ref. 5):

$$C\ddot{\theta} + \frac{3}{2}(B-A)\frac{GM}{r^3}\sin 2\Psi = 0 \qquad (1)$$

where G is the gravitational constant and M is the mass of the Sun. From Fig. 1 we find $\theta = f + \Psi$. Suppose we wish to determine the stability of a planetary spin angular velocity near $pn/2$, where n is the mean motion of the planet and p is any integer. Defining a new angle $\gamma = \theta$

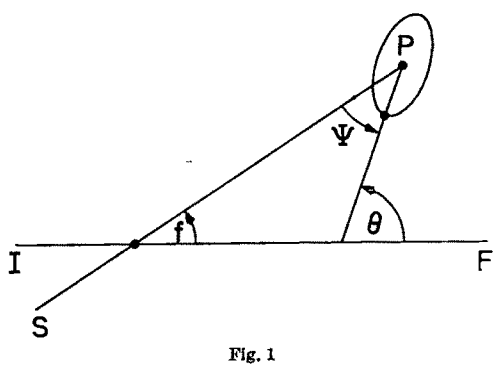

Fig. 1

$-pnt/2$ (where $t=0$ at $f=0$), we may average equation (1) over an orbit period keeping γ fixed since it only varies slightly during this period. Including terms up to second order in e, we have:

$$C\ddot{\gamma}+\frac{3}{2}(B-A)n^2 \sin 2\gamma\left[-\frac{e}{2}\delta_{p1}+(1-\frac{5}{2}e^2)\delta_{p2}+\frac{7}{2}e\,\delta_{p3}+\frac{17}{2}e^2\,\delta_{p4}\right]=0 \quad (2)$$

where δ_{pq} is the Kronecker delta. From equation (2), which is the ordinary pendulum equation, we observe that in the absence of tidal torques a planet will exhibit stable librations at values of $\dot{\theta}=n/2,\ n,\ 3n/2,\ 2n$. (Higher order commensurabilities are also stable, but they involve higher powers of e.) For the first case ($\dot{\theta}=n/2$) stability occurs for oscillations about $\gamma=\pi/2$, or in other words, at perihelion the short axis of the planet points approximately towards the Sun. In the other cases oscillations occur about $\gamma=0$, and the long axis is approximately pointing toward the Sun at perihelion. The synchronous rotation corresponds to $\dot{\theta}=n$, whereas $\dot{\theta}=3n/2$ is the rotation state which Colombo has proposed for Mercury.

It is natural to question the stability of these commensurate spin states when tidal torques are present. Now the averaged tidal torque ($-T$) must be added to the right-hand side of equation (2). For a given p we have:

$$C\ddot{\gamma}+\frac{3}{2}(B-A)\,f(p,e)\,n^2 \sin 2\gamma=-T \quad (3)$$

when $f(p,e)$ is the coefficient of the appropriate Kronecker delta in equation (2). ($f(p,e)$ is either 0 or of the order $e^{|p-2|}$.) In cases where Q is frequency independent and $\dot{\theta}$ is greater than the instantaneous orbital angular velocity at perihelion, T is constant (that is, T is independent of γ, $\dot{\gamma}$ and t). Equation (3) is now the pendulum equation with an additional applied constant torque. For stability the applied torque must not exceed the maximum possible restoring torque which occurs at γ displaced by $\pi/4$ from its equilibrium value. Thus the stability criterion is:

$$T<\frac{3}{2}(B-A)\,f(p,e)n^2 \quad (4)$$

We can apply this condition to examples provided by the solar system.

For the Moon in its present orbit with the known value of $(B-A)/C=2\times10^{-4}$, all the commensurabilities we have discussed as well as some depending on terms of higher order in e are stable. The commensurabilities occur for both faster and slower rotations than the present synchronous rotation of the Moon. Even if the Moon were much closer to the Earth, with a smaller orbital eccentricity, some of the higher order commensurabilities would still be stable. For Mercury the value of $(B-A)/C$ is unknown. However, for values as small as 10^{-8} and probably even 10^{-9} the $\dot{\theta}=n/2$ and $\dot{\theta}=2n$ commensurabilities would be stable. With such an exceedingly small deviation from axial symmetry which is necessary for stability in the $n/2$ and $2n$ modes, the question arises as to how Mercury and the Moon could have passed through either of these states to reach their present ones. It seems exceedingly likely that Mercury and the Moon must have passed through one or the other of the adjacent stable commensurate spin states to attain their present spins. Similar strong indications that satellites may pass through these resonances are provided by the observed synchronous rotations of several satellites of the major planets. Of special interest is Iapetus because of its weak tidal torque, relatively high orbital eccentricity, and well-confirmed synchronous rotation[6]. Equation (3) provides a probable explanation of this behaviour.

If we multiply equation (3) by $\dot{\gamma}$, the left-hand side is dE/dt, where E is the energy integral of the pendulum equation. Since:

$$\frac{dE}{dt}=-T\dot{\gamma} \quad (5)$$

we see that a constant tidal torque will not damp the amplitude of a libration about the minimum energy value of γ. Thus, while the commensurate spin rates are stable for sufficiently weak tidal torques, any initial libration about the stable value of γ will persist indefinitely. On the other hand, if any term in T is proportional to $\dot{\gamma}$ we see that these librations will be damped.

Now consider the rotation of a non-axisymmetric planet as tidal friction slows its spin from a rate which is several times n. As the spin of the planet slows it must approach one of these stable commensurabilities. We cannot determine definitely from our approximate analysis whether libration about the stable value of γ will ensue or whether the planet will pass through this commensurability and continue to 'de-spin'. However, as the amplitude of any libration about a stable commensurate spin is not damped from its initial value of $\pi/2$ by a constant tidal torque, this marginally stable condition cannot persist, and the planet must eventually escape from this commensurability and continue to 'de-spin'. However, a term in T proportional to $\dot{\gamma}$ would tend to damp the libration and trap the planet in a high-order commensurability. Even in this case it may be possible for the planet to escape from the commensurability before the damping has been sufficient to trap it. This has actually occurred in some numerical calculations performed by one of us[7].

From the examples provided by the Solar System it seems that Mercury, the Moon and several other satellites known to be synchronous have successfully avoided being trapped in higher order commensurabilities in spite of the small permanent asymmetry required to stabilize these states. This conclusion holds even for initially retrograde spins, since stable commensurabilities exist for retrograde rotations as well. Mercury may be in the $3n/2$ resonance. Because of its large orbital eccentricity, the spin angular velocity corresponding to the 59-day period is actually slower than the instantaneous orbital angular velocity at perihelion. Thus the tidal torque on Mercury reverses twice during each orbit which leads to a term equal to a positive constant times $\dot{\gamma}$ in the average tidal torque (even if the torque is constant between reversals). As explained previously this term produces a damping of the librations in γ and hence may stabilize the rotation of Mercury in the $3n/2$ commensurability. Thus the reversal of the tidal torque discussed by Peale and Gold[2] seems to be a necessary condition for the trapping of Mercury's spin into the 3/2 commensurability. In other words Mercury can be in the 3/2 commensurability but only because the tidal friction tends to bring it there. Otherwise it would have passed through this commensurability as it has apparently escaped others. It should be emphasized that no strong limit on the permanent deformation or rigidity of Mercury is required by either the final state of $\dot{\theta}=3n/2$ or the final state determined by the gravitational tidal friction alone. Barring trapping in any of the higher order commensurabilities (which seems possible only for Mercury), we find that the planet will end up spinning either synchronously or at the slightly faster rate discussed by Peale and Gold (see ref. 8). Because of the aforementioned reversal of tidal torque, librations about synchronous rotation are damped regardless of eccentricity.

IONIZATION RELAXATION IN SLIGHTLY IMPURE ARGON

By Dr. N. R. JONES* and Dr. M. McCHESNEY
Department of Mechanical Engineering, University of Liverpool

In recent years there have been several experimental investigations of the growth of ionization behind strong shock waves in the noble gases: all these have suggested that impurities in the gas can significantly influence the time taken to reach equilibrium ionization. At the time of writing, however, there was no satisfactory quantitative theory existing assessing the role of these impurities.

The most widely quoted investigation of this problem is that of Petschek and Byron[1]. They suggested that the change of the degree of ionization α with time t in the initial ionization stage where the first free electrons are produced was entirely due to the presence of impurities and given by:

$$\frac{d\alpha}{dt} = (1 - \alpha)^2 A N_I \exp\left(-\frac{T_{ACT}}{T}\right) \quad (1)$$

where A and T_{ACT} are constants to be found from experiment, while N_I is the impurity species number density and T is the relaxing translational temperature. When equation (1) is combined with their proposed final ionization stage rate then they obtain an ionization time τ given by:

$$\tau = \int_0^{\alpha^*} \frac{d\alpha}{(1-\alpha)^2 A N_I \exp\left(-\frac{T_{ACT}}{T}\right) + N_A B \alpha^2 \ln\left(\frac{\alpha_{EQ}}{\alpha}\right)} \quad (2)$$

Here N_A is the neutral atom number density, B is given in graphical form in the reference cited while α_{EQ} is the equilibrium degree of ionization. It should be noted that τ is not an ionization relaxation time since we cannot in general define a true exponential approach to equilibrium throughout the entire relaxation zone (see Clarke and McChesney, ref. 2). Petschek and Byron found $A = 8 \times 10^{-8}$ cm^3/sec and $T_{ACT} = 11{\cdot}5$ eV for argon.

Several criticisms of this investigation can be made: (i) Their (modified) frequency factor A is too high; this follows, since simple kinetic theory permits us to write:

$$A = \left(\frac{2kT}{\pi\mu}\right)^{\frac{1}{2}} Q_{IA}\left(1 + \frac{T_{ACT}}{T}\right) \quad (3)$$

where μ is the reduced mass of the argon atom–impurity species collision complex while Q_{IA} is the cross-section for the collision process the activation 'temperature' of which is T_{ACT}. The Petschek–Byron value for T_{ACT} when combined with a cross-section as large as 10^{-17} cm^2 (see below) still yields an A value three orders of magnitude smaller than the Petschek–Byron value; no sensible juggling with the variables of equation (3) can be made to yield an A value anywhere near 10^{-8} cm^3/sec. (ii) A value of $T_{ACT} = 11{\cdot}5$ eV is that corresponding to excitation of an argon atom whereas it should be the activation energy of an easily excited impurity. It should be noted that Petschek and Byron do not actually state that the impurities react through a cumulative mechanism as is commonly implied. (iii) They neglect the possibility of concurrent argon atom–argon atom excitation collisions. (iv) They claim that impurities are important over all shock Mach numbers and obtain an ionization time always significantly dependent on the impurity level; however, their experimental results at a shock fore-pressure of 10 torr using argon containing an impurity of 1 part in 10^3 are identical with their results for an impurity-level of 5 parts in 10^5.

The experimental investigations of Johnston and Kornegay[3] and Harwell and Jahn[4] show that initial ionization in a pure gas will proceed cumulatively and not in a single step as proposed by Bond[5]. This has been supported by Weymann[6], who proposed a two-step mechanism for ionization, namely, impact excitation and then impact ionization. It is likely that this proposed two-step mechanism is correct, but the simple kinetic considerations used by Weymann are incorrect. Neither Harwell and Jahn nor Johnston and Kornegay quantitatively discuss impurities while Weymann incorrectly assesses their role in the same way as did Petschek and Byron. We shall use the two-step ionization mechanism for the following concurrent reactions in the initial stage of ionization:

$$Ar + Ar \xrightarrow{k_A^*} Ar^* + Ar \longrightarrow Ar^+ + e^- + Ar \quad (4)$$

$$I + Ar \xrightarrow{k_I^*} I^* + Ar \longrightarrow I^+ + e^- + Ar \quad (5)$$

$$I^+ + Ar \rightleftharpoons I + Ar^+ \quad (6)$$

We shall utilize the final stage ionization mechanism used by Petschek and Byron. Their corresponding ionization rate expression is inaccurate and more detailed calculations are in hand by one of us (M. Mc.) on the electron energy balance in this regime. These coupled processes yield an ionization time:

$$\tau = \int_0^{\alpha^*} \frac{d\alpha}{(1-\alpha^2) N_A\left(k_A^* + \frac{N_I}{N_A} k_I^*\right) + N_A B \alpha^2 \ln\left(\frac{\alpha_{EQ}}{\alpha}\right)} \quad (7)$$

which should be compared with equation (2). The significant difference between our equation (7) and the Petschek–Byron equation (2) is that the former considers concurrent excitation processes: as we shall note, this results in the ionization time being considerably less sensitive to the impurity level at high Mach numbers than suggested by Petschek and Byron.

The intermediate excited level of the noble gas is taken as the first metastable level: any further cumulative excitation will not be rate controlling; photo-excitation is inadmissible to this level—as is spontaneous de-excitation. Due to the high inter-particle collision frequency and very low radiation density in the near-visible radiation field, photo-ionization of the metastable state is negligible as will be induced emission processes. Furthermore, calculations not discussed here show that due to the relatively low concentration of excited levels, collisions between two excited atoms are negligible. We are obliged to ignore cascade transitions due to paucity of oscillator strength data for ArI. Following Petschek and Byron we ignore all recombination processes since the analysis is only applied up to a degree of ionization α^* where recombination is still secondary.

In equation (7) the k^* factors are reaction rate constants given by:

$$\frac{1}{2}\left(\frac{2\pi kT}{\mu}\right)^{-\frac{3}{2}} \int_{g_0}^{\infty} \exp\left(-\frac{\mu g^2}{2kT}\right) Q(g) 4\pi g^3 dg$$

where apart from standard symbols, g is the relative velocity of the colliding species, $Q(g)$ is the velocity dependent inelastic cross-section and $\frac{1}{2}\mu g_0^2 = \frac{1}{2}kT_{ACT}$ which for a step-function form of cross-section yields the right-hand side of equation (3): this is a better form for heavy particle inelastic collisions near threshold than the ramp function suggested by Harwell and Jahn (see following). We can ignore the ionizing collisions given by the second part of the reactions described in equations (4) and (5); this steady-state approximation is justifiable

* Present address: Imperial Chemical Industries, Ltd., Runcorn.

from the experimental investigations to be reported here as well as on theoretical grounds since it is known that the cross-sections for the ionizing collisions are large and of order of the momentum transfer cross-sections (see Hirschfelder and Eliason, ref. 7).

The experimental values of the ionization time were measured in a combustion-driven shock tube using a Mach–Zehnder interferometer. The difficulties attached to time-resolved optical interferometry due to the small overall fringe shifts occurring and the speed at which they change together with the complications due to the self-luminosity of the shock-heated gas were largely overcome by utilizing the photo-electric monochromator technique for recording the fringes described by Jones and McChesney[8]. Fig. 1 shows values of $p_1\tau^*$ (where p_1 is the shock fore-pressure and τ^* is the total time taken to reach equilibrium) plotted versus T_{AO}, the reciprocal of the post-shock unrelaxed translational temperature together with the values predicted by Petschek–Byron theory. A complete description of the diagnostic techniques used together with the method of analysis of the results is given by Jones[9]. It will be seen that Petschek–Byron theory overestimates the role of impurities at all Mach numbers M_s and also that the total time to reach equilibrium ionization is insensitive to the impurity level (within sensible limits) above Mach 12. Analysis yielded the following results: the excitation cross-section for the first part of the reaction given by equation (4) is $2{\cdot}5 \times 10^{-18}$ cm^2 for a known activation energy of 11·6 eV. Noble gas excitation cross-sections of this size have been reported by Harwell and Jahn and also Johnston and Kornegay without comment: however, their large size merits comment.

Bates and Massey[10] have made Born approximation calculations of heavy particle impact excitation and ionization collisions and found them to be of order 10^{-22} cm^{-2} or less at threshold: of course, the Born approximation is likely invalid at very low energies since it makes all inelastic collisions near adiabatic. The low-energy beam experimental investigations of Amme and Hayden (private communication) yield an ionization cross-section for direct impact ionization of argon by another argon atom that rises like a step function from a value of 5×10^{-20} cm^2 at a relative kinetic energy of 28 eV to a (approximately) constant value of about 10^{-16} at 105 eV. There are no corresponding excitation cross-sections (either emission or absolute) in this energy range reported in the literature: the only neutral particle excitation data of any relevance are those of van Eck *et al.*[11], whose results suggest that the large excitation cross-sections are possible if intermediate molecule formation occurs in the collision complex with its corresponding multiplicity of potential energy surfaces allowing an excitation jump.

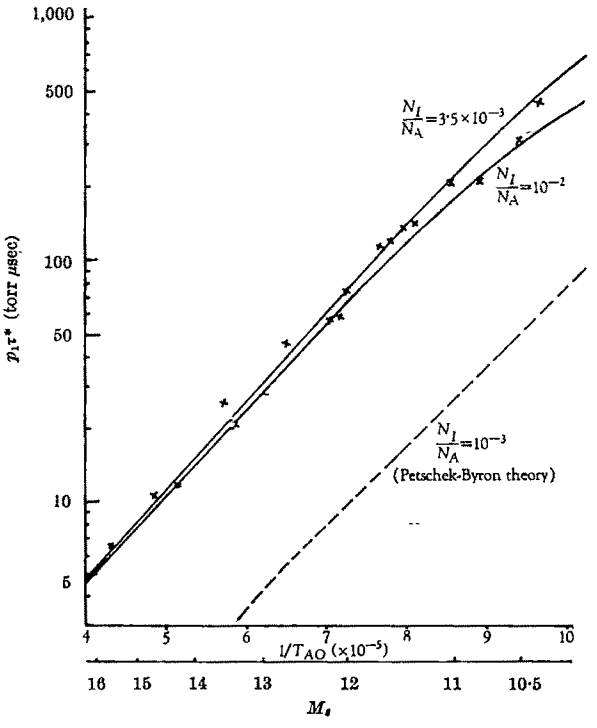

Fig. 1. Equilibrium ionization times as a function of shock fore-pressure, p_1, shock Mach number, M_s and reciprocal post-shock unrelaxed translational temperature, $1/T_{AO}$. Solid lines are given by equation (7); ×, experimental points

A full discussion of the excitation and charge exchange cross-sections together with the nature of the impurity atoms and the possible role of chemi-ionization reactions in the ionization process will appear elsewhere.

We thank N. G. Utterback for suggestions and advice, and the National Physical Laboratory for a grant. One of us was the recipient of a D.S.I.R. research studentship during this work.

MANGANESE-54: FRACTIONAL DISTRIBUTION IN WHEAT AND OCCURRENCE IN OTHER FOODS

By DORIS C. SUTTON and JOHN J. KELLY

Health and Safety Laboratory, U.S. Atomic Energy Commission, New York

MANGANESE-54 (^{54}Mn), a neutron activation product, was detected in fall-out samples from Eniwetok testing grounds in 1956 (ref. 1). The distribution pattern of manganese-54 during that period and of other radioactive non-fission products such as iron-55, iron-59, cobalt-57, cobalt-58 and cobalt-60, and zinc-65, was estimated from measurements on whole plants and animals by means of γ-ray spectrometry. Generally, these radionuclides were found in sea water and some marine animals, but were undetected in marine plants. Few or none were detected on the ground, in plants growing in the soil, or in herbivorous field animals[2]. In 1961 and 1962, large amounts of manganese-54 were found in debris from a series of atmospheric nuclear weapons tests. From these tests, measurements of manganese-54 by γ-ray spectrometry have been reported in samples of grain and food[3].

Stable manganese was detected in many parts of plants and in several organs of animals and humans more than 50 years ago, and was found, with few exceptions[4], in all substances analysed. The concentrations of stable man-

ganese reported in animals and humans were appreciably less than those observed in plants. In experiments with wheat seedlings, Burstrom[5] found manganese salts to be unique when compared with salts of the alkali, alkaline earth, and heavy metals, in that assimilation or conversion of nitrate to plant protein was effected only in the presence of this element. This observation and later findings confirmed that stable manganese was an essential minor element for the normal growth of plants. In studies of other natural elements that are minor but essential and important in crop production, namely, iron, zinc, copper, and cobalt, Robinson[6] found that there was little variation in the accumulation in plants of any of these except manganese. Besides investigations of plant nutrition and crop production in relation to stable manganese, a considerable amount of work has been done towards establishing the chemical forms and reactions of manganese in soil. It is generally agreed that stable manganese exists in the soil in several chemical forms. Briefly these forms are: (1) manganous manganese (Mn^{+2}), which usually exists in an exchangeable form between soil and plants; (2) manganic manganese (Mn^{+3}), which is easily reduced by bacterial action within the soil; (3) the manganese oxides, which include various structural types and oxidation states. The availability of these various forms of manganese to plants is dependent on several environmental factors, such as soil type, hydrogen ion and anion concentration, organic constituents, bacterial action and seasonal variation[7–11].

The specific chemical form of radio-manganese in fallout is unknown but is generally assumed to occur mainly as inert manganese dioxide. No evidence is available as to whether atmospheric weathering or existing soil conditions provide an environment favourable to reducing this oxide to forms available for plant uptake. Thus, during the work on two fission products, cerium-144 and caesium-137, in 10 g of ash from samples of the 1963 United States wheat crop[12], we separated manganese for detailed investigation using radiochemical and instrumental methods.

The radiochemical procedure and the instrumental techniques used for the measurement of manganese-54 and stable manganese were as follows. Equilibration of stable manganese and radiomanganese was accomplished by extracting the sample ash with a mixture of hydrochloric acid and hydrogen peroxide. Manganese dioxide was separated from the sample matrix with strong nitric acid and sodium chlorate. The precipitate was dissolved, transferred to a small vial, and manganese-54 measured by γ-ray counting with a single-channel analyser[13]. Under standard conditions, the counting efficiency for manganese-54 was 20 per cent. The error due to counting for the tabulated values was within 10 per cent. The disintegration rate of manganese-54 was determined from the counting rate and corrections were made for background, efficiency, and decay. Purity was established by counting the samples in groups, using a 256-channel γ-ray analyser with an 8 × 4 in. sodium iodide (Tl) crystal over a range from zero to 3 MeV. Only the characteristic 0·84-MeV peak of manganese-54 was observed from the spectrum of each group, with a small contribution from the 1·40-MeV peak of potassium-40, which was inherent to the crystal. As a further means of establishing the purity of the samples, the group γ-ray spectra were resolved graphically, using a method based on the use of an integral spectrum. The latter technique, using the integral spectrum rather than the differential spectrum, offered the advantage that the resolved spectra are linear with unit slope when plotted on logarithmic paper[14]. Graphs of each of the group spectra indicated a single-component system.

Stable manganese was determined spectrophotometrically in the original sample as permanganate after periodate oxidation[15]. Measurements were made using a model '*DK*-2' Beckman spectrophotometer with maximum absorption at 525 mμ. The actual amount of stable manganese present in each sample was determined separately by taking a 1-g portion of the sample ash through the radiochemical procedure after adding a known amount of manganese-54. The tracer was used to determine the overall chemical recovery, and a sample portion was then analysed spectrophotometrically. The latter value was used to correct the yield of the 10 g of ash from the original sample. Average chemical recoveries were 95 and 80 per cent, respectively, for the 1-g and 10-g portions of ash.

The amounts of manganese-54 and stable manganese found in samples of the 1963 United States wheat crop from eleven states are shown in Table 1. These states produced about 75 per cent of all the wheat grown in the United States during 1962 with Kansas producing 20 per cent of this. The value for each State is reported at a time considered to be the mid-point of the harvest.

The concentrations of manganese-54 and stable manganese, and consequently the ratio of picocuries of manganese-54 to milligrams of stable manganese, were fairly constant with three exceptions. The samples from Missouri and South Dakota accumulated a relatively larger amount of stable manganese than was found for other samples and the Ohio sample showed the smallest uptake of stable manganese. Neither of these apparent extremes is unusual for stable manganese accumulation in healthy plants, and this variation may be the result of prevailing soil conditions.

For an investigation of the balance of distribution of the radionuclide, a Kansas wheat sample was separated into its milling fractions. As shown in Table 2, the distributions of the measured manganese-54 and stable manganese are remarkably similar for all fractions. The concentration of this stable element and its radionuclide was larger in the inner layer shorts fraction (55 and 52 per cent respectively) than in the bran fraction which forms the outermost layers of the wheat kernel (35 and 39 per cent respectively). The patent flour fraction which is used for human consumption contained 4 per cent manganese-54 and stable manganese. From this distribution pattern it seems that rapid exchange occurred between radio-manganese and natural manganese and that uptake has been through the root of the plant rather than as a result of physical adherence of inert radio-manganese.

In order to estimate the occurrence of manganese-54 in the 1964 diet, ten food samples were selected from the open market in May 1964 in New York City and measured for manganese-54 and stable manganese. The values are reported as of the middle of the sampling month in Table 3. Manganese-54 was detected in small amounts in fresh

Flour	62	5·7
White bread	12·8	3·1
Whole wheatbread	132	28·5

* Less than or equal to single Poisson counting error.

fruit and fresh vegetables. It was not detected in a sample of root vegetables that contained carrots, onions, and turnips, or in a separate sample of potatoes. Neither was it detected in rice. It was found in almost equal amounts, 60 pc./kg, in dry beans and white flour. The amounts of manganese-54 and stable manganese measured in whole wheat bread were approximately ten times higher than the amounts found in white bread. The ratio of picocuries of manganese-54 to milligrams of stable manganese for whole wheat bread and white bread was 4·6 and 4·1, respectively. Since the specific activity of manganese in the 1964 bread samples was much lower than can be accounted for by radioactive decay, assuming a 310-day half-life, in the representative 1963 wheat sample, it can only be assumed that the 1963 crop was not the sole origin of wheat for the 1964 diet. The fact that the specific activity showed good agreement for whole wheat and white bread further substantiates exchange between manganese-54 and stable manganese.

The ten food samples shown in Table 3 represent approximately 35 per cent of the total yearly diet[16]. Assuming a corresponding amount of manganese-54 for the entire diet, though it is believed that this estimate is high, an intake of about 160 pc. manganese-54 per week may be postulated for the general population in 1964. Since the maximum permissible intake for chronic exposure to manganese-54 is approximately 4,000 pc. per week for the general population[17], the amounts found in the 1964 foods are not considered to constitute a health hazard.

TOPOTACTIC DEHYDRATION OF BRUCITE

By R. R. BALMBRA, DR. J. S. CLUNIE and DR. J. F. GOODMAN

Basic Research Department, Procter and Gamble, Ltd., Newcastle upon Tyne

SINGLE crystals of brucite, naturally occurring $Mg(OH)_2$, may be dehydrated topotaxially[1] to periclase, MgO. $Mg(OH)_2$ has a layered structure of the CdI_2 type and may be described as consisting of hexagonally close-packed hydroxide ions with the small Mg^{++} ions occupying octahedral interstices between alternate sheets, . . . *AmB AmB* . . . . Since no hydrogen bonds exist in the structure[2] we may consider the lattice arrangement in terms of close-packed oxygen atoms. The pseudomorphic dehydration product, MgO, is based ideally on a cubic close-packed oxygen framework with the small cations occupying all the octahedral interstices, . . . *AmBmCm* . . . . From a knowledge of the initial and final structures it has been possible to discuss plausible mechanisms for the dehydration process[3].

In a recent kinetic investigation of this transformation[4] it was suggested that certain differences may exist between thermal decomposition and the decomposition observed by one of us, using the beam of an electron microscope[5]. Accordingly, we have examined the purely thermal decomposition of brucite *R* (ref. 4) (kindly supplied by Dr. P. J. Anderson) using electron microscopy and selected-area electron diffraction. Specimens were prepared from crystallites, scraped from a cleavage face, which were deposited on a carbon support film. The dehydration was performed at 320° C in an electric furnace at a pressure less than 10^{-4} mm of mercury. At various stages during the 3–4 h required for complete reaction, specimens were slowly cooled to room temperature and examined in a Siemens 'Elmiskop 1'. Electron diffraction patterns taken with the electron beam parallel to the [001] direction of brucite revealed that under normal operating conditions the original $Mg(OH)_2$ showed no decomposition in the electron beam (Fig. 1*a*). The crystallographic and

a *b* *c*

Fig. 1. Electron diffraction patterns from (*a*) original $Mg(OH)_2$; (*b*) intermediate phase; (*c*) final dehydration product, MgO

morphological changes occurring during the thermal decomposition were the same as those observed previously by decomposition in the electron beam[5]. It seems reasonable to conclude that the decomposition in the electron beam is caused primarily by the rise in temperature of the specimen, irradiation effects apparently being of only minor importance.

After heating for 15 min, a well-defined spot pattern due to the previously reported intermediate phase was obtained (Fig. 1*b*). Thus, by controlled heating the intermediate structure can be recognized as a separate phase, which under normal conditions does not revert to brucite. The nature of this intermediate structure provides an important clue to the decomposition mechanism. Since decomposition temperatures greater than 800° C may ultimately produce traces of a spinel-type by-product it has been tentatively proposed[6] that heating causes a migration of cations within the close-packed oxygen lattice. This idea of cation migration can readily explain the present electron diffraction data. As the filling of tetrahedral interstices is regarded as highly unlikely at moderate temperatures because of the unfavourable radius ratio parameter, the migrating Mg^{++} ions must enter the unfilled octahedral holes which exist between alternate sheets in the ideal $Mg(OH)_2$ structure. Local electrical neutrality within the new structure will then be preserved by protons diffusing into those regions from which there has been a loss of Mg^{++} ions. Whether discrete water molecules are formed within the structure at this stage is uncertain but seems probable. What is certain is that, at this primary stage, kinetic experiments reveal no loss of water[4]. The previously observed lattice shrinkage[5] of about 5 per cent relative to brucite was observed in the (*hk*.0) plane of the hexagonally symmetric intermediate phase. Like the isostructural $Ca(OH)_2$ (ref. 7) it seems probable that in $Mg(OH)_2$ the octahedra of oxygen atoms surrounding each cation are compressed along the hexagonal axis, the compressional force presumably arising from the asymmetry of the electrostatic environment in the layered lattice rather than from any steric factor. The migration of Mg^{++} ions into the previously unfilled interlayer interstices in the hexagonally close-packed oxygen lattice will relieve the original electrostatic compression and result in the observed compensating lateral contraction within the (*hk*.0) plane. In descriptive terms, the intermediate phase may be considered to possess a highly defective NiAs type structure with only half the total available octahedral sites occupied by Mg^{++} ions, that is, a cation-deficient structure somewhat analogous to that possessed by the $CoTe_x$ system ($1 \leqslant x \leqslant 2$) (ref. 2). The discrete but diffuse nature of the spots in the (*hk*.0) single crystal diffraction pattern of the intermediate phase (Fig. 1*b*) is characteristic of a structure possessing interstitial disorder and possibly also stacking faults. Direct evidence for the existence of stacking faults in the intermediate structure is provided by the occurrence in some of the diffraction patterns of a weak hexagonal network of diffuse streaks joining the reciprocal lattice nodes.

In the second, slow stage of the decomposition, which occurs on further heating, the hexagonal pattern of the intermediate phase gradually fades, leaving only those strong but diffuse spots due to the cubic MgO structure (Fig. 1*c*). During this stage there is (i) the transition from a predominantly hexagonal to cubic close-packing of oxygen atoms via dislocations and their resulting stacking faults, and (ii) the loss of half the total number of oxygens as water vapour. The diffusion-controlled loss of water from the structure along dislocations[8] is envisaged as occurring from those regions of the intermediate phase which are deficient in Mg^{++} ions. The final structure will be highly porous, which explains the unusually high specific surface areas found for dehydrated $Mg(OH)_2$ crystals by gas adsorption studies[4]. The discrete but diffuse spots in the diffraction pattern for MgO (Fig. 1*c*) indicates that the overall final structure may be considered a highly imperfect single crystal.

To determine the *c*-crystallographic dimension of the hexagonal intermediate structure, X-ray powder photographs were obtained from partially decomposed $Mg(OH)_2$. The resulting diffraction patterns were complex, containing sharp rings due to the unchanged $Mg(OH)_2$ ($a = 3{\cdot}15$ Å, $c = 4{\cdot}74$ Å), diffuse rings due to the porous decomposition product MgO ($a = 4{\cdot}19$ Å), and weak, arced lines which can be ascribed to small equilibrium amounts of the intermediate phase ($a = 2{\cdot}98$ Å, $c = 4{\cdot}83$ Å). A few additional, very weak, arced lines were observed in the 2–5 Å region which do not correspond to reflexions from the ideal hexagonal lattice of the intermediate phase. All but one of these subsidiary reflexions can be ascribed indices (00.*l*) having half integral *l* values indicating that the length of the unit cell in the *c*-direction is double that of the fundamental spacing. This observation is compatible with the presence of stacking sequences in the close-packed oxygen layers of the type . . . *ABAC* . . . . The remaining 'extra' line corresponds to a (00.*l*) reflexion with *l* one-third integral, indicating the presence of domain regions with a layer stacking of the type . . . *ABCACB* . . . (ref. 9). The existence of such stacking faults is consistent with our proposed decomposition mechanism. Thus, as in the analogous γFeO(OH) system[10], the proposed decomposition mechanism clearly demonstrates that the transformation does not involve any *de novo* crystallization of the reaction product but is controlled solely by the close-packed anion arrangement of the initial structure.

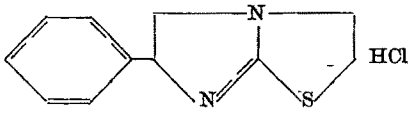
TETRAMISOLE (*R* 8299), A NEW, POTENT BROAD SPECTRUM ANTHELMINTIC

By D. THIENPONT, O. F. J. VANPARIJS, A. H. M. RAEYMAEKERS, J. VANDENBERK, P. J. A. DEMOEN, F. T. N. ALLEWIJN, R. P. H. MARSBOOM, C. J. E. NIEMEGEERS, K. H. L. SCHELLEKENS and PAUL A. J. JANSSEN

Janssen Pharmaceutica, n.v., Research Laboratoria, Beerse, Belgium

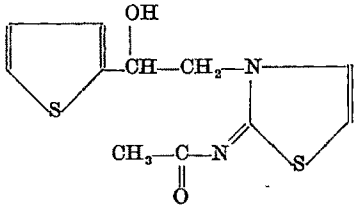
THIS article reports the discovery of tetramisole (*R* 8299 (I)), a new, potent broad spectrum anthelmintic, which is at present undergoing large-scale clinical trials in several countries.

In the course of our routine screening programme for anthelmintic activity the aminothiazol derivative (II) (thiazothienol or *R* 6438) was found to be active against *Heterakis*, *Ascaridia* and *Capillaria* in the chicken.



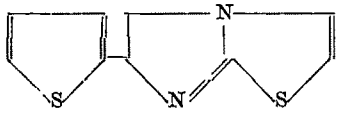
The major metabolite of (II) was isolated from the faeces, and tentatively identified as the imidazothiazole-derivative (III) (*R* 8025). Its structure (III) was confirmed by chemical synthesis and found to be fully active

in removing *Heterakis*, *Ascaridia* and *Capillaria* in the chicken as well as a variety of gastrointestinal and pulmonary nematodes in sheep—and at significantly lower dose-levels than its parent compound (II).

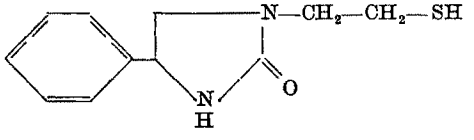


An extensive series of chemically related compounds was later synthesized and screened for anthelmintic, pharmacological and toxicological activity.

As a result of these investigations tetramisole (I) (*R* 8299), the white, stable and water-soluble (21 per cent at 20° C) crystalline hydrochloride of 2,3,5,6-tetrahydro-6-phenyl-imidazo[2,1-*b*]thiazole, emerged as the most promising substance for detailed investigation as a potential anthelmintic.



These investigations showed tetramisole (I) to be active at low, atoxic dose-levels against adult and immature gastrointestinal and pulmonary nematodes tested in this laboratory (Table 1), both by the oral route (drench, capsule, in drinking-water or in feed) and by subcutaneous, intramuscular or intraperitoneal injection.



(I)

(I) *R* 8299, tetramisole, $C_{11}H_{12}N_2S.HCl$, m.p. 264° C. 2,3,5,6-tetrahydro-6-phenyl-imidazo[2,1-*b*]thiazole hydrochloride.

(II) *R* 6438, thiazothienol, $C_{11}H_{12}N_2O_2S_2$, m.p. 133° C, 2-(acetylimino)-3-[2-hydroxy-2-(2-thienyl)-ethyl]-thiazoline.

(III) *R* 8025, $C_9H_8N_2S_2$, m.p. 62° C, 5,6-dihydro-6-(2-thienyl)-imidazo[2, 1-*b*]thiazole.

(IV) *R* 9280, $C_{11}H_{14}N_2OS$, m.p. 88° C, 2-oxo-3-(2-mercaptoethyl)-5-phenyl-imidazolidine.

Depending on the worm species and on the type of host, the optimal therapeutic dose of tetramisole varies from 2 to 40 mg per kg body-weight, orally or parenterally, most nematodes being removed with one single dose. (In this article all doses of tetramisole are expressed in mg of the base per kg body-weight. One mg of the base is the equivalent of 1·18 mg of the hydrochloride salt.)

Low concentrations of tetramisole exert a rapid paralysing action *in vitro* on a variety of nematodes such as *Heterakis*, *Ascaridia*, trichostrongylids, *Trichuris*, *Chabertia* and *Bunostomum*.

Critical tests and large-scale field experiments in chickens have shown that a single oral dose of 40 mg tetramisole per kg body-weight (in capsule, drinking-water or feed) expels 97–100 per cent of all immature and adult forms of *Ascaridia galli*, *Heterakis gallinarum* and *Capillaria obsignata* within 24 h. No undesirable effects were observed after oral administration of up to 640 mg/kg. There is no depression of egg production at therapeutic dose-levels. Full activity against the three common nematodes in the chicken has not yet been described with any other drug.

Critical tests in naturally infected lambs and sheep showed tetramisole (5–20 mg/kg orally, subcutaneously or intramuscularly) to be fully effective in a large majority of the animals against adult and immature forms of *Trichostrongylus*, *Ostertagia*, *Cooperia*, *Haemoncus*, *Nematodirus*, *Strongyloides*, *Oesophagostomum*, *Bunostomum*, *Chabertia*, *Trichuris* and *Dictyocaulus*. * Data from this laboratory.

† Information communicated by: 1, Benazet, F., Graber, M. 2, Bruynooghe, D. 3, Davey, D. G., Forsyth, B. A., Froyd, G., and Walley, J. K. 4, Goennert, R., Federmann, M., and Meister, G. 5, Martins Campos J, V., and Viterito, I. A. 6, Nilsson, O. 7 Pouplard, L 8, Roveda, R. J , and Galofré, E. J 9, Waletzky, E.

gastrointestinal worm burden is expelled within the first 24 h and most of the lungworms within the first 12 h after administration.

Within the first 6 h after treatment, the most rapidly expelled worms, for example *Dictyocaulus*, *Chabertia* and *Bunostomum*, are often detected alive, whereas nematodes expelled later are dead and partially decomposed. No side-effects or evidence of local irritation were observed after administration of therapeutic doses of up to 40 mg/kg orally or up to 10 mg/kg parenterally. With higher doses (40 mg/kg subcutaneously or 80 mg/kg orally) transient side-effects, including hyperpnoea, salivation and lacrimation, occurred in a few animals and subsided within 1 or 2 h. Clonic seizures and mortality were observed with much higher doses. Therapeutic doses were well tolerated in pregnancy. There were no abortions or malformations.

Very similar results were obtained in cattle, tetramisole showing high activity against all gastrointestinal and pulmonary nematodes tested, that is, *Trichostrongylus*, *Ostertagia*, *Cooperia*, *Nematodirus*, *Trichuris* and *Dictyocaulus viviparus*. There were no undesirable effects with a single dose of 5 or 10 mg/kg orally or parenterally.

In mongrel dogs and in beagles, a single oral dose (capsule) of 20 mg/kg of tetramisole was fully effective against *Toxascaris* and *Toxocara*, highly active against *Uncinaria* and marginally active against *Trichuris*. A 3 per cent incidence of vomiting was noted at this dose-level. With 40 mg/kg orally or 20 mg/kg subcutaneously emesis occurred in about half of the animals. Administration of 20 mg/kg daily during 8 weeks failed to produce evidence of toxicity in beagles.

The anthelmintic spectrum of tetramisole seems to be limited to the various species of nematodes. No activity was detected against cestodes (for example *Moniezia* in sheep) or trematodes (for example *Fasciola hepatica* in sheep).

Tetramisole was also inactive against a series of fungi *in vitro* (*Mucor* sp, *Sporotrichum schenckii*, *Phialophora verrucosum*, *Saprolegnia* sp, *Aspergillus fumigatus*, *Candida albicans*, *Candida tropicalis*, *Cryptococcus neoformans*, *Microsporum canis*, *Trichophyton mentagrophites* and *Trichophyton rubrum*). The compound was equally inactive *in vivo* against *Microsporum canis* and *Trichophyton mentagrophites* (guinea-pig). Tetramisole is devoid of antibacterial activity *in vivo* (*Streptococcus pyogenes*, *Erysipelothrix rhusiopathiae*, *Salmonella pullorum gallinarum*). *In vivo* no activity was observed against *Trichomonas vaginalis* (mice), *Trichomonas columbae* (pigeons) and *Eimeria* infections (sheep, chicken).

Tetramisole is furthermore devoid of antihistaminic, anticholinergic, adrenolytic or any other classical pharmacological property.

In laboratory animals, clonic seizures are observed at sub-lethal and lethal dose-levels. The following acute $L.D._{50}$'s (in mg/kg; $P < 0{\cdot}05$ confidence limits) were obtained by probit analysis :

Route	Albino mouse	Wistar rat
Intravenous	22 (16– 29)	24 (19–29)
Subcutaneous	84 (58–123)	130 (94–181)
Oral	210 (156–284)	480 (361–638)

The daily administration in feed of an average of 9 and 35 mg/kg of tetramisole for 120 consecutive days in Wistar rats of both sexes had no significant effect on food consumption, growth rate, a number of parameters of blood and urine biochemistry, haemograms, organ weights or tissue histology. Depression of food consumption and of growth rate was seen at a daily dose-level of 140 mg/kg.

In alkaline conditions, tetramisole slowly hydrolyses to form 2-oxo-3-(2-mercaptoethyl)-5-phenyl-imidazolidine (IV), a water-insoluble neutral crystalline solid. (IV) also appears to be one of the major metabolites of tetramisole in several species. It is devoid of anthelmintic activity and almost atoxic.

The work described in this article is part of a programme on heterocyclic compounds, a programme supported by a grant from the Instituut tot Aanmoediging van het Wetenschappelijk Onderzoek in Nijverheid en Landbouw (IWONL).

AUTORADIOGRAPHIC EVIDENCE SUGGESTING *in vivo* TRANSFORMATION OF SOME BLOOD MONONUCLEARS IN REPAIR AND FIBROSIS

By Dr. T. GILLMAN and L. J. WRIGHT

Department of Experimental Pathology, Agricultural Research Council Institute of Animal Physiology, Babraham, Cambridge

MAXIMOW'S well-known views on the pluripotentiality of lymphocytes scarcely require documentation here[1]. Until 3 or 4 years ago this opinion of Maximow's was held by few pathologists[2–5] and discredited by many[6,7]. However, in recent years, many investigators have established, beyond reasonable doubt, that, at least *in vitro*, some lymphocytes can be stimulated either by phytohaemagglutinin (PHA) or by suitable antigens, to transform into large and possibly pluripotential-looking 'blast' cells which may later mitose[8]. Moreover, Hall and Morris[9] have described apparently similar cells in efferent ducts from lymph nodes stimulated antigenically *in vivo*, and even in afferent lymph draining peripheral tissues into which antigens had been injected. This latter finding, and the increase in lymph-borne antibody associated with the appearance of such 'blast-like' and later also 'plasma-like' cells in lymph[9] leave little doubt that activation, transformation and mitosis of small lymphocytes (and possibly of other cells, too) is a regular response of these cells *in vivo* as well, at least after antigenic stimulation.

However, the finding of these notable changes in lymphocytes by immunologists seems to have led to the impression that such activation and transformation of lymphocytes is essentially and solely to be found in immune responses. Maximow's broader claims for the potentialities of lymphocytes have still to be substantiated by modern objective methods—as opposed to the more usual subjective cytodiagnostic evidence pressed forward to Maximow's support by many investigators—including one of us[2].

However, almost a decade ago, a careful re-examination of the histogenesis of healing wounds in man and animals[10] led one of us to conclude that: ". . . All the available evidence . . . indicates that the new fibroblasts, which develop during the healing of connective tissues in cutaneous wounds, are derived primarily from cells which have migrated from the circulation, or which have been derived from the peripheral tissue surrounding blood vessels and the *residual* portions of the stratum papillari of the dermis about hair follicles . . . ". This view was, in general, later confirmed by Grillo[11] using tracer techniques.

As part of a series of investigations into the factors determining and regulating wound healing and fibrogenic processes in general, it was thought desirable to examin-

once more, and with modern techniques, the timing of the cellular changes preceding the onset of fibrogenesis in wounds and around implanted foreign bodies.

Several authors[11,12] have, in recent years, reported that when cells were labelled with tritiated thymidine, injected just prior to killing their previously wounded animals, the isotope was taken up first in cells cuffing small vessels in sites of injuries. It is around these vessels, too, that, in healing wounds, mitotic figures have often been reported to appear first[13]. Such mitoses have been stated to occur in perithelial cells or local fibrocytes but not in 'round cells'[11,12]. No significance and certainly no subsequent fibroblastic role were attributed by these investigators to the numerous 'round cells' (lymphocytes and monocytes) generally recognized to appear regularly during one phase of the inflammatory reaction which consistently precedes fibrogenesis in healing wounds or around foreign bodies.

Recently, Volkman and Gowans[14,15] reported that monocytic cells, named macrophages by them (whether or not they contained ingested material—see Gillman and Gillman[2] for criteria for naming 'macrophages' and other connective tissue cells), were present in large numbers 24 h after making Rebuck-type skin windows. These authors clearly demonstrated that a far greater percentage of mononuclears were labelled if the isotope was injected 18 to 24 h before making the 'windows' and that very few cells were labelled 24 h post-operatively if rats were injected only post-operatively. They concluded that these labelled 'macrophages' were derived from circulating monocytes which, they claimed, originated from cells previously labelled in bone marrow and which were then transported by the blood to the skin windows.

We have recently confirmed Volkman and Gowans's findings that a far greater number of round cells (lymphocytes and monocytes), which accumulate in sites of injury, carry label if isotope is injected 18 h prior to inflicting the injury than if the isotope is given only post-operatively (see Fig. 1 and legends to Figs. 2 and 3).

However, Volkman and Gowans did not follow, beyond 24 h post-operatively, the fate of the many labelled blood-derived mononuclears which appear perivascularly in injured tissues within a day or two of trauma. Their observations were confined to the first 24 h after preparing skin windows in rats that had received tritiated thymidine at various times pre- and post-operatively.

Our experiments were designed to determine what relationship, if any, exists between injury, the invariable post-traumatic inflammation, and the subsequent genesis of new fibrous tissue—a subject which, in our view, has hitherto received too little attention. This aspect of pathology seems to be of fundamental importance for our understanding, in any tissue or organ, of both inflammation in general and of fibrogenesis in particular. For, while acute inflammatory processes often resolve, those following trauma may, and frequently do, herald the onset of repair and thus often precede fibrogenesis (see Gillman, 1963, for distinction between repair and regeneration)[16]. Thus, post-traumatic inflammation is very commonly followed by the early supervention of features generally described as 'sub-acute' or 'chronic' inflammation and characterized by fibroplasia.

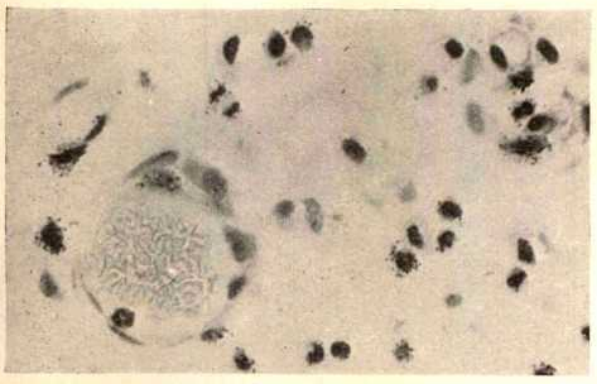

Fig. 1. Autoradiograph of dilated vessels at base of a full thickness excised wound in a pre-operatively labelled rat 24 h after wounding, showing distribution of labelled extravascular round cells, presumably blood-borne mononuclears that have emigrated from dilated venules. One of these labelled round cells, well away from the perithelium, is in mitosis. Very few equivalent round cells in post-operatively labelled rats contain label at this time. Haematoxylin and eosin counterstain on autoradiograph. Exposed for 61 days (×*c.* 550)

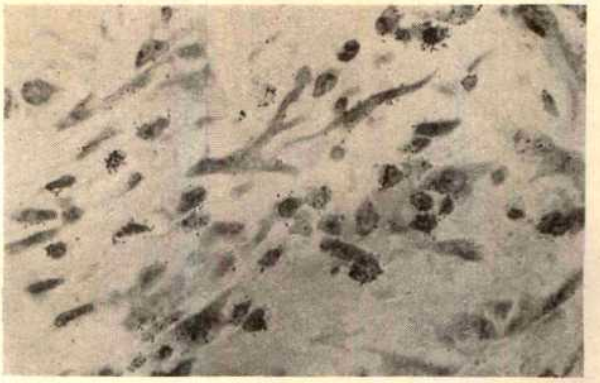

Fig. 2. Autoradiograph of granulations in 3-day-old wound from a pre-operatively labelled rat. Note here numbers of labelled mononuclears and, near top centre, two clearly labelled fibroblastic-like cells, one spindle-shaped and one stellate. Stained with haematoxylin and eosin, and exposed for 61 days (×*c.* 550)

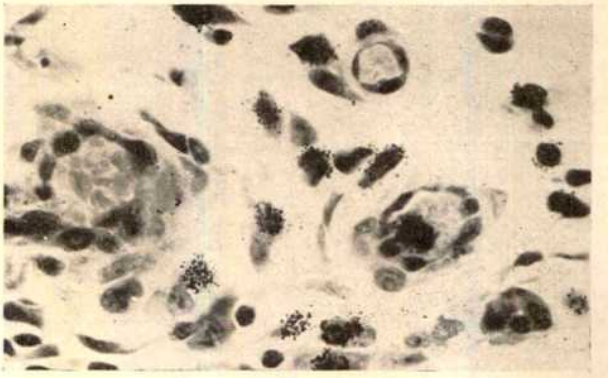

Fig. 3. Autoradiograph of base of granulations in 3-day-old wound from post-operatively labelled rat. Note location and morphology of heavily labelled cells—some clearly mononuclears and others (top) stubby and spindle-shaped. Compare distribution and morphology of labelled cells here with those in Figs. 1 and 2. Perithelial cells are not notably labelled. Stained with haematoxylin and eosin and exposed for 61 days (×*c.* 550)

As part of our efforts to elucidate what determines the invariable transition of inflammation to fibrogenesis, in healing wounds and around foreign bodies, we conducted two sets of experiments. In both types of experiments tritiated thymidine was used as the tracer because: (*a*) it is incorporated into nuclear DNA just before mitosis; (*b*) it has, therefore, been taken generally (and we think in some situations incorrectly) to be an excellent indicator of cells about to enter mitosis; (*c*) being intranuclear, it is a 'tight' label; re-utilization of the isotopic thymidine for DNA synthesis being, at most, very slight and always very slow. In both types of experiments 1 cm diameter excised, full thickness wounds were made in the back skin (through panniculus carnosus to deep fascia) and, in each of the same rats, small polyvinyl sponges and 'Millipore' filters were implanted in a distant site, subcutaneously and/or intraperitoneally.

The experiments differed in one important detail. In one series of rats the tritiated thymidine was injected pre-operatively, intravenously, either once, 18 h, or twice,

namely 18 and 5 h pre-operatively. The rats received no further isotope post-operatively and were killed at intervals from 1 to 25 days after the operations. It was hoped that such pre-operative labelling would provide some indications of the types of cells appearing at different times after injury, the movements, and also the ultimate fate of those cells which must have been labelled themselves, or were descendants of cells labelled before inflammatory and fibrogenic changes had been initiated.

The second group of previously unlabelled rats were operated on and then only one intravenous injection of the same dose of isotope (1 μc./g body-weight) was given post-operatively just 2 h before killing the rats. Thus, in this second group of rats, labelling was post-operative, being confined to the 2 h before death, because it is widely accepted that such 'flash' or 'pulse' labelling with thymidine would mark only those cells which had just synthesized new DNA immediately before dividing. However, as will emerge later, it is reasonable to expect some label also in the daughter cells derived from progenitors that had utilized the tritiated thymidine before mitosis and which, by subsequent mitosis, had given rise, just before death, to two very new, albeit less heavily labelled descendants.

Imprint or touch preparations were made of portions of the granulation tissue which formed in the excised wounds, and of the sponges, filters, spleen, lymph nodes, and bone marrow of all experimental animals. These imprints were made, on specially cleaned slides, according to the method previously described[2]. The slides were fixed in C.P. methanol for at least 24 h (to eliminate the possibility of autochemograms) covered with '*NTB* 2' emulsion by dipping and, after exposure for periods varying from 14 to 114 days, were developed and stained by the Giemsa method fully described by Speirs[17] with minor modifications. Autoradiographs were similarly prepared of serial paraffin sections of all the aforementioned tissues, the sections being stained through the emulsion with haematoxylin and eosin after developing the autoradiographs.

In rats injected with isotope only post-operatively, that is, 2 h before killing, notable labelling of cells in the lesions studied was first seen only between 24 and 48 h after operation. By the third day label was most obvious in lymphocytes and monocytes cuffing small venules in sites of injury and in some of the endothelial cells of these same vessels. However, at this time, too, labelled mononuclears were occasionally seen even within the lumina of arterioles or venules in the injured areas (Fig. 3). This is not totally unexpected since Volkman and Gowans, and we too, have found that 0·5 to, at the most, 1 per cent of blood mononuclears are labelled even within 1–2 h after such isotope injections. This finding is important, however, since it strongly suggests that the labelled perivascular cells, shown in Fig. 3, may well be a mixed population comprising local cells entering mitosis but also of already labelled emigrated blood-borne cells—recent arrivals on the scene. However, the number of labelled round cells in injured areas, in post-operatively labelled rats, became very much greater between the third and fourth post-operative days, but comprised maximally only about 15 per cent–20 per cent of all cells in imprints or sections. Thus, in animals killed 3–7 days post-operatively, but injected only 2 h before death, large numbers of cells were labelled—including, in addition to those already mentioned, spindle-shaped fibroblast- and fibrocyte-like cells (Figs. 3, 5 and 7). These results would seem to confirm, in general, those of MacDonald[12] and of Grillo[11], who, however, considered the majority of their labelled fibroblasts to be locally derived.

In contrast, rats injected with isotope once, or better twice, pre-operatively only, when examined even at 24 h post-operatively, manifested label in 40–80 per cent of perivascular round cells within and/or around the wounds, sponges or filters (Fig. 1). It was easily possible, on Giemsa-stained imprints, to compare these cells with those in the smears of blood and haemapoietic organs from the same animals, and hence, in the initial stages of the inflammatory reaction, to classify them, on haematological criteria, as lymphocytes or monocytes. Very occasionally on the first day (Fig. 1), but more consistently and frequently by the second and third days post-operatively (and, incidentally, therefore, more than 2–3 days after the last dose of isotope) these labelled mononuclears, well removed from perithelium, could be seen to be in mitosis (Fig. 1) and to acquire morphological features seemingly indistinguishable from those described as typical of small lymphocytes activated *in vitro* (see foregoing).

It might be added, in passing, that a small but regular percentage of cells, generally acceptable on morphological grounds to be fibroblasts and fibrocytes, with label in their nuclei, were consistently identified in these rats killed 3, 7 or even up to 14 days after the last dose of pre-operatively injected label (Figs. 2, 4 and 6). The same applied also to the multinucleated giant cells[18].

Since the round cells, in the one group of rats, had obviously been labelled well before the inflammatory and fibrogenic processes were initiated, they were clearly brought to the injured tissues by the blood. Emigration of blood mononuclears and granulocytes is, of course, an accepted aspect of inflammation. Such pre-operatively labelled mononuclears, or their descendants, appeared to arrive in cohorts, each at increasing times after isotope injections and subsequent wounding, and, therefore, with the expected progressively decreasing amounts of nuclear label resulting from repeated 'dilution' in their daughter cells after mitosis (compare Figs. 1, 2 and 4). Thus, we have found the bone marrow to be virtually depleted of

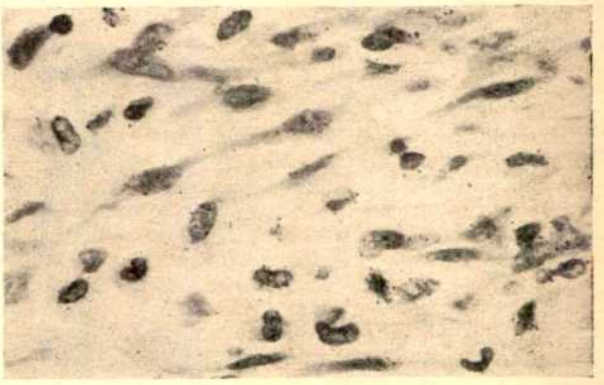

Fig. 4. Fibroblast-like and mononuclear cells in base of granulations in 7-day-old wound in pre-operatively labelled rat. Label intensity is less than at earlier times presumably due to 'dilution' of label by repeated mitosis of cells labelled pre-operatively, that is, 7 days and 5 h previously. Stained with haematoxylin and eosin, and exposed for 61 days (×*c.* 550)

Fig. 5. Labelled spindle-shaped cells, taken to be fibroblasts, at surface of granulations immediately below new epithelium (seen, in part, at top). At this stage, 7-day-old wounds, labelled fibroblasts are predominantly near surface in post-operatively labelled animals and near base after pre-operative labelling. Stained with haematoxylin and eosin, and exposed for 61 days (×*c.* 550)

labelled nuclei by the sixth or eighth day after the last dose of isotope—a finding in conformity with Volkman and Gowans's results. It could, therefore, not be expected that the ultimate labelling of 7-day fibroblasts in pre-operatively labelled rats would be as intense as in rats injected with isotope only 2 h before death.

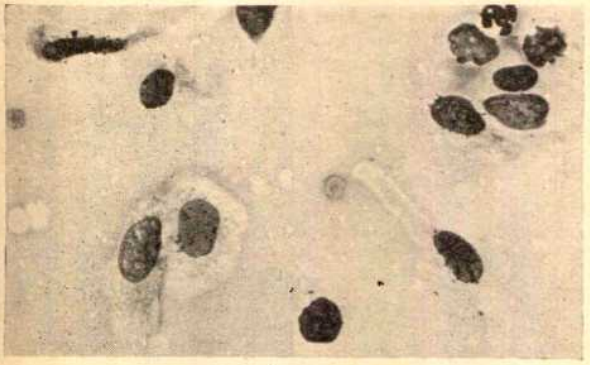

Fig. 6. Two fields from an imprint preparation of the capsule of a 7-day-old subcutaneous sponge from an animal last injected with label 7 days and 18 h previously. At left, top, a heavily labelled nucleus in a spindle-shaped fibrocyte with below, right, a lightly labelled large histiocytic cell with vesicular nucleus. At right, centre, another moderately labelled spindle-shaped fibrocyte with, above, a labelled mononuclear (? lymphocyte) nucleus. Differences in intensity of nuclear label attributed to mitotic 'dilution' of lighter labelled cells. Stained with Giemsa. Autoradiograph prepared by exposure for 28 days (× *c.* 550)

Many of these pre-operatively labelled round cells, after emigrating into sites of injury, became phagocytic; many apparently moved away from the inflammatory sites—both acceptable findings confirming recent observations[19]. But many also remained in the injured sites for days and even weeks (Fig. 5), and some of these clearly became transformed first into blast-like or mitosing cells (Fig. 1) and afterwards even into cells indistinguishable from fibroblasts and fibrocytes (Figs. 2, 4 and 6).

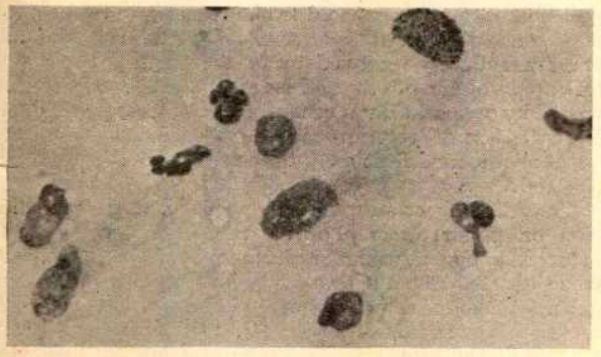

Fig. 7. Two heavily labelled fibroblasts (one top, one centre) from a 7-day-old wound of a post-operatively labelled rat. Compare with Figs. 4, 5 and 6. Since fibroblasts near the surface are most heavily labelled with post-operative tritiated thymidine injections (see Fig. 5) they come off readily in imprints. Not so with pre-operatively labelled rats in which basal fibroblasts, as in Fig. 4, are labelled and are surrounded by collagen. Stained with Giemsa and exposed for 42 days (× *c.* 550)

The connective tissues, in sites other than those specifically injured, were always sampled by us at the time of the operation and were found to be virtually unlabelled, except for a relatively small number of cells around hair follicles and occasionally in the panniculus carnosus. However, we are not concerned here with either of the latter since, in our excisions, both the entire dermis and the panniculus were resected, while implants were always deep to the panniculus carnosus.

It is clear, therefore, that some of the blood mononuclears, which are consistently borne by the blood to injured sites, 24–48 h after operation, remain in the zones of fibrogenesis and apparently later undergo notable morphological changes. That these cells also prepare to mitose soon after they arrive is indicated, at 48–72 h post-operatively, by the frequent and notable uptake of label when tritiated thymidine is first given only shortly before death (compare Figs. 1 and 3).

This seems to be strong evidence to show that, after their emigration, activation of circulating blood mononuclears and their transformation into blast-like and mitosing cells are common in the acute inflammation which regularly precedes fibrogenesis in wounds and around foreign bodies. Of course, it is quite possible that such transformation, in tissues, of emigrated blood monocytes (apparently primarily) and perhaps also of blood lymphocytes, may be in response to antigen inadvertently introduced with the foreign bodies at the time of operation, or derived from damaged tissues. This possibility cannot be overlooked in view of Hall and Morris's[9] findings already noted. However, the persistence, in fibrosing areas, of pre-operatively labelled blood mononuclears, and the subsequent frequency of labelled fibrocyte-like cells, to be described in detail in future investigations, leaves little doubt that activation and transformation, extravascularly, of emigrated blood mononuclears, that is, monocytes and/or lymphocytes, is an integral aspect of fibrogenesis and not solely the prerogative of uncomplicated immunological responses.

These findings, therefore, lead us to suggest that blood-borne mononuclear cells can become activated *in vivo* and undergo morphological changes, similar to lymphocytes *in vitro*, at least in sites of fibrogenesis. It is clearly shown that a population of cells can be labelled pre-operatively, somewhere in the body (according to Volkman and Gowans in bone marrow), which afterwards becomes borne by the blood to sites of injury. Once they have emigrated into the injured tissues these cells may: (1) become phagocytes and later leave the reaction sites; (2) remain in the area, become activated and mitose; (3) be found in the injury up to 14 days following the trauma (and 15 days after the last isotope injection) when some of them become morphologically indistinguishable from classical stellate fibroblasts or spindle-shaped mature fibrocytes; (4) fuse to form multi-nucleated foreign-body-type giant cells[18].

It should be added here that no unequivocal evidence emerged from our investigations of preferential labelling or mitotic activity in perithelial cells. Our evidence indicates that emigrating labelled blood mononuclears, which may mitose when still near the perithelium (Fig. 1) or which, while motile and hence elongated, resemble perithelium and become arranged concentrically around vessels (Fig. 3), have perhaps been mistaken by other workers to be mitosing perithelium.

The evidence here presented thus seems to provide objective support for Maximow's contention that at least one pluripotential cell does indeed exist in circulating blood. Whether this pluripotential blood-borne cell is the monocyte or lymphocyte (or both) is not established by our experiments; the findings of Volkman and Gowans at least seem to indicate that their monocytic cells come from bone marrow rather than from spleen or lymph nodes. Our results certainly do not indicate that fibroblasts are derived only from circulating mononuclears; the latter, however, do seem to give rise to a proportion of fibrocytes in sites of repair.

These findings suggest that blood-borne mononuclears may, in appropriate circumstances, 'switch on' either antibody or collagen synthesis. If so, these observations may have considerable implications for further investigations of repair and sclerosis of many organs and tissues and perhaps of the relationships between immune responses and fibrosis.

Pure Chemistry Library, SCIENCE COLLEGE

In summary then it can be stated that:

(1) Using autoradiographs of serial sections and imprints of tissues, a comparison has been made of the localization, numbers, morphology and intensity of nuclear labelling of cells in healing excised wounds and implanted sponges or 'Millipore' filters in rats injected, intravenously, with tritiated thymidine either only pre-operatively or only immediately before killing on various days post-operatively.

(2) It has been shown that, during the first 2 days, a far greater number of labelled blood leucocytes appear in sites of injury and fibrosis in rats receiving isotope pre-operatively only. Pre-operatively labelled mononuclears (that is, lymphocytes and monocytes) or their descendants emigrate from the local vessels, migrate into the local fluid exudates, mitose and undergo transformations into macrophages and other cell forms.

(3) No evidence emerged to support the widely held views that perithelial cells play any significant part in fibrosis.

(4) Blood mononuclears, labelled pre-operatively only, or their descendants (less heavily labelled by virtue of isotope 'dilution' following mitosis) have been shown to be present in fibrosing sites even up to 14 days post-operatively. The frequent existence of cells, morphologically indistinguishable from fibroblasts and fibrocytes, with labelled nuclei, many days after the last isotope injection, taken with the localization, cytology, movements and apparent transformation of mononuclears labelled pre-operatively, is considered to indicate that at least some fibroblasts, in healing wounds and chronic inflammatory processes, may be derived from some blood-borne pluripotential cell(s).

(5) Activation, transformation and mitosis of blood mononuclears has, in recent years, been described and generally taken to be a primarily immunological reaction. The data reported here indicate that similar changes in blood mononuclears occur *in vivo* in those inflammatory responses which precede fibrosis. The implications of these findings for understanding the pathogenesis of 'subacute' and 'chronic' inflammation and the fibrogenesis related thereto, in many organs and tissues, are briefly discussed.

FORMATION OF ADENOSINE TRIPHOSPHATE BY HUMAN ERYTHROCYTE GHOSTS

By GUNNAR RONQUIST and Prof. GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

It was previously reported from this laboratory[1,2] that small amounts of phosphorus-32 labelled adenosine triphosphate ($AT^{32}P$) were formed by human erythrocyte ghosts on incubation for a short time with radioactive orthophosphate ($^{32}P_i$). It has been suggested[3,4] that a glyceraldehydephosphate dehydrogenase–phosphoglycerate kinase enzyme complex may be the mediator of active phosphate transport into the human erythrocyte. This implies that the $AT^{32}P$ formation would be enhanced if ADP and other co-factors were added to the medium. In the present article, some experiments are described which indicate that the ATP is formed in ghosts in the phosphoglyceraldehyde dehydrogenase and phosphoglycerate kinase reactions.

A soluble fraction was obtained from red cell ghosts, which had been washed six times with water saturated with carbon dioxide, by extracting them six times with a 0·016 M *tris*-glycylglycine buffer, *p*H 8·2. The pooled extracts were purified by 'Sephadex' filtration[1,2] and used for the following experiments. The ghost residues remaining after extraction were also tested for their ability to form $AT^{32}P$. The soluble membrane fraction or ghost residues (ghosts) from 100 ml. to 150 ml. whole blood were incubated in 0·05 M *tris*-acetic acid buffer, *p*H 7·5, for different times with 2 μmoles of $^{32}P_i$ having a radioactivity of 2 mc. The final volume was 20 ml. Unless otherwise stated, the following substances were added in addition to $^{32}P_i$: 25 μmoles magnesium chloride, 10 μmoles nicotine amide, 10 μmoles cysteine, 5·9 μmoles glyceraldehyde 3 phosphoric acid (3-GAP), 3·5 μmoles nicotinamide-adenine dinucleotide (NAD), 35 μmoles of ADP and 200 μmoles of *tris*-acetic acid buffer, *p*H 7·5. All incubations were carried out at 37° C. The reaction was stopped by addition of 50 per cent cold trichloroacetic acid (w/v) to a final concentration of 5 per cent. The trichloroacetic acid was immediately removed by extracting five times with an equal volume of ethyl ether. The solution was concentrated by evaporation *in vacuo*, and chromatographed on a 'Dowex 1 × 2' column according to Hurlbert *et al.*[5], with slight modifications[6] to enable the $AT^{32}P$ to be isolated.

The $AT^{32}P$ fraction was further identified after purification on paper electrophoresis in 0·1 M pyridine-acetic acid, *p*H 5, by analysing for phosphorus[7], ribose[8], and base[9] constituents. Fig. 1 shows a typical 'Dowex 1' chromatogram of the trichloroacetic acid extract from a $^{32}P_i$-incubated membrane fraction (only the phosphorus compounds eluted after $^{32}P_i$ are shown). The ATP formed in the experiments was estimated radio-chemically by measuring the incorporation of $^{32}P_i$ into ATP and by analysing the total amount of phosphorus in the ATP fraction and finally, by measuring the ultra-violet absorbancy at 260 mμ. The molar absorbancy[10] was assumed to be $14·9 \times 10^3$. The nitrogen content of the membrane fraction, ghosts and haemolysate was determined by a micro-Kjeldahl method.

Evidence for the presence of the enzymes glyceraldehydephosphate dehydrogenase and phosphoglycerate kinase in erythrocyte ghosts was obtained in the following experiments. Ghosts were incubated with and without 3-GAP, in addition to the other substances in the afore mentioned medium. In a control experiment, ghosts were incubated with only $^{32}P_i$. $31·9 \times 10^{-5}$ μmoles of phosphate/mg nitrogen was incorporated into the AT

when 3-GAP was also present. When a similar incubation was performed without 3-GAP in the medium, $1{\cdot}2 \times 10^{-5}$ μmoles of phosphate/mg nitrogen was incorporated into the ATP. The corresponding figure for the control incubated with only $^{32}P_i$ was $0{\cdot}95 \times 10^{-5}$ μmoles/mg nitrogen. The addition of 3-GAP thus increased the synthesis of ATP twenty-six times.

For comparison, another series of experiments was performed with ghosts which had been washed six times with carbon dioxide–water and those which, in addition, had been extracted six times with the alkaline *tris*-glycylglycine buffer. Haemolysate, filtered through 'Sephadex *G* 25' to remove low molecular weight compounds, was also included. The haemolysate was concentrated by ultrafiltration to about a tenth of its original volume by the same technique as that used for concentrating the membrane fraction[1]. The ATP synthesized, expressed as the phosphate incorporation into ATP in μmoles of $^{32}P_i$/mg nitrogen, was lowest for the haemolysate (Table 1). The highest incorporating activity, however, was recorded in the haemolysate fraction.

Table 1. Incubation of Ghosts (see text) and Haemolysate

ATP synthesis expressed as the phosphate incorporation into ATP in μmoles $^{32}P_i \times 10^5$/mg nitrogen.

A	*B*	*C*
118	85	17

Total incorporation of phosphate into ATP in μmoles $^{32}P_i \times 10^5$.

A	*B*	*C*
2,124	1,235	4,930

Each of the three fractions corresponds to 15 ml. of packed red cells. Incubation time, 6 min. *A*, Ghosts only washed six times with carbon dioxide–water. *B*. Ghosts washed six times with carbon dioxide–water, as well as six times with the *tris* glycylglycine buffer. *C*, Haemolysate (after haemolysis 1 : 10) eluted through 'Sephadex *G* 25' with 0 05 M *tris*-acetic acid buffer, *p*H 7 5, and concentrated about ten times.

Table 2 shows the formation of ATP expressed as the incorporation of $^{32}P_i$ into ATP in μmoles of $^{32}P_i$/mg nitrogen. It is seen that the membrane fraction content of ATP increased progressively with time during the first 4 h, whereas in the ghosts there was a rise up to 6 min, followed by a decline. It is possible that this difference was due to the presence of ATPase in the ghosts[11] and its absence in membrane fraction[1,2].

de Verdier[12] has shown that there may be a rapid exchange of phosphate groups between inorganic phosphate and the terminal phosphate group of ATP in haemolysates of human red blood cells. The following experiments were performed to provide additional evidence of a *de novo*

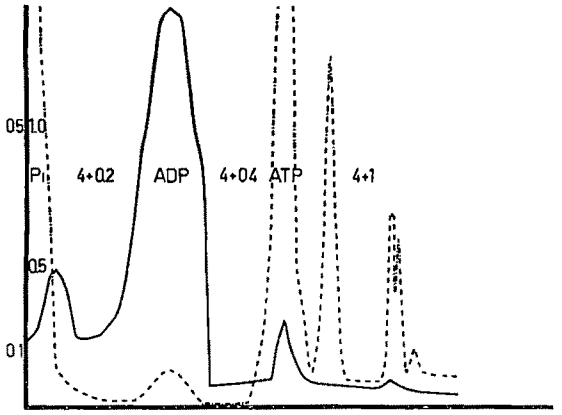

Fig. 1. 'Dowex 1' chromatogram of the trichloroacetic acid extract of the incubated membrane fraction. 20 ml. membrane fraction incubated for 4 min with 2 μmoles of $^{32}P_i$, 25 μmoles of magnesium chloride, 10 μmoles of nicotinamide, 10 μmoles of cysteine, 5 9 μmoles of 3-GAP, 3·5 μmoles of NAD, 35 μmoles of ADP and 200 μmoles of *tris*-acetic acid buffer, *p*H 7·5. The phosphorus compounds were eluted stepwise as follows: 4 N formic acid, 0·2 M ammonium formate + 4 N formic acid, 0 4 M ammonium formate + 4 N formic acid, 1 M ammonium formate + 4 N formic acid. ·····, Radioactivity; ———, ultra-violet absorbancy at 260 mμ. Numbers on the left of the *y* axis are c p m./ml. × 10^{-3} and those on the right the ultra-violet absorbancy at 260 mμ. The *x* axis represents the tube number

Table 2. Comparison between Membrane Fraction and Ghosts

	Membrane fraction	Ghosts
10 sec	2·0	13·7

Membrane fraction and ghosts incubated for various times with orthophosphate and co-factors (see text). ATP synthesized, expressed as the phosphate incorporation into ATP in μmoles $^{32}P_i \times 10^5$ mg nitrogen

synthesis of ATP in red cell ghosts. 80 ml. of the membrane fraction was incubated with 8 μmoles of $^{32}P_i$, 100 μmoles of magnesium chloride, 40 μmoles of nicotinamide, 40 μmoles of cysteine, 23·6 μmoles of 3-GAP, 14 μmoles of NAD, 158 μmoles of ADP and 1,000 μmoles of *tris*-acetic acid buffer, *p*H 7·5. After 4 min, 20 ml. of the fraction was removed and precipitated at once with trichloroacetic acid. At the same time, 2 μmoles of P_i was added to the remaining solution (60 ml.). The operation was repeated twice at 4-min intervals with the addition of 1·3 μmoles of P_i and 0·6 μmoles of P_i to the remaining membrane fraction in the first and second repetitions, respectively. The final 20-ml. portion was precipitated with trichloroacetic acid after a 4-min incubation period. The trichloroacetic acid extract from each of the four fractions was chromatographed on a 'Dowex 1' column as already described, and the tubes corresponding to the maximal values of the ATP fraction were selected for measurements from the recorded curves for ultra-violet and phosphate content. The incorporation of $^{32}P_i$ into the total ATP fractions was also measured, as well as the phosphate content. The figures in Table 3 demonstrate a *de novo* synthesis of ATP.

Table 3

	4 min	8 min	12 min	16 min
μmoles ATP/ml.	0·0032	0·0043	0·0057	0·0067
Total phosphorus, μmoles/ml.	0·010	0·016	0·018	0·022
Total phosphate incorporation into ATP fraction in μmoles $^{32}P_i$	0·023	0·033	0·0482	0 0612
Total phosphate content of ATP fraction in μmoles P_i	0 076	0·122	0 162	0·199

80 ml. of the membrane fraction was incubated with 8 μmoles of $^{32}P_i$, 100 μmoles of magnesium chloride, 40 μmoles of nicotinamide, 40 μmoles of cysteine, 23·6 μmoles of 3-GAP, 14 μmoles of NAD, 158 μmoles of ADP and 1,000 μmoles of *tris*-acetic acid, *p*H 7 5. Every 4 min, 20 ml. was removed and immediately precipitated in trichloroacetic acid. At the same intervals, unlabelled orthophosphate was added to the rest in an amount of 2·0, 1·3 and 0·6 μmoles, respectively.

The ultra-violet absorbancy and phosphate content were determined in the tube of the ATP fraction with maximum values.

These results agree with our view that human erythrocyte ghosts synthesize ATP. The mechanism by which ATP is formed in human erythrocyte ghosts is likely to be through oxidative phosphorylation on a substrate-level by way of the enzymes glyceraldehydephosphate dehydrogenase and phosphoglycerate kinase.

PURIFICATION AND LABILITY OF HUMAN FOLLICLE-STIMULATING HORMONE

By Dr. S. M. AMIR and Dr. S. A. BARKER
Department of Chemistry, University of Birmingham
AND
Dr. W. R. BUTT and Dr. A. C. CROOKE
Department of Clinical Endocrinology, The United Birmingham Hospitals

THE starting materials for the present investigations were obtained from acetone-dried human pituitary powder by the method of Butt, Crooke and Cunningham[1]. Most of the luteinizing hormone (LH) was removed from the follicle-stimulating hormone (FSH) by absorption on a column of *CM*-cellulose. The first fraction (*CM* 1) eluted from this column with 0·01 M ammonium acetate at *p*H 6·1 contained the FSH. Two fractions, *CP* 1 and *CP* 2, were next obtained from *CM* 1 by elution from calcium phosphate with 1 mM disodium hydrogen phosphate and 0·02 M disodium hydrogen phosphate, respectively, without the previous recommended intermediate step of chromatography on DEAE-cellulose since it was found that this is better effected later using the DEAE-'Sephadex' equivalent. The calcium phosphate fractionation removed much inactive protein and some of the remaining LH.

The amounts of FSH in *CP* 1 and *CP* 2 were in the ratio of 100 : 13 and only 1 per cent of the total activity was lost in another fraction, *CP* 3, obtained by elution with 0·02 M trisodium phosphate. Much of the activity of *CP* 2 was recovered by passage down a column of 'Sephadex *G*-100' (36 × 3·5 cm) eluted with water. The fractions (5 ml.) were scanned for extinction at 280 mμ and showed two peaks with maxima at fractions 10 and 28. The FSH was mainly located in the pooled fractions 8–12 and 13–18, which were of equal potency. The total $E_{280m\mu}$ of these two fractions, 1·43 and 0·62, respectively, did not reflect the biological activities. Fractions 19–25 contained 37 per cent and fractions 26–32 only 17 per cent of the FSH activity of each of the first two fractions.

Passage of *CM* 1 down the same column confirmed that FSH was eluted just after the exclusion volume (fractions 11–17) and that the second ultra-violet peak contained little FSH.

Further purification of FSH was effected on a column of DEAE-'Sephadex' (34 × 3·5 cm) eluted in 5-ml. fractions with 0·005 M phosphate buffer, *p*H 7·0, with a salt gradient to 0·8 M sodium chloride. There was one major ultra-violet peak at 0·41 M sodium chloride (fraction 85) and several smaller ones. The LH activity was mainly confined to fractions 77–79 and FSH activity mainly to fractions 83–87. The FSH activity was not uniformly distributed about the ultra-violet peak but was eluted more in the earlier fractions.

Up to this point the fractions had been dialysed and the protein recovered by freeze-drying; however, the enrichment of FSH activity per mg was not progressing at the rate predicted from the yields of activity and the weights of the fractions, and furthermore the overall yields from a given fractionation were low. This was particularly so when the FSH fraction from DEAE-'Sephadex' was passed down a second column of DEAE-'Sephadex' and only 40 per cent of the FSH activity was recovered. Investigations showed that this could be directly attributed to a major loss of activity occurring during freeze-drying.

Fraction *CP* 1 passed down a column of DEAE-'Sephadex' retained complete activity when stored as eluted at −40° C for 20 h. Subsequent freeze-drying caused an overall loss of 42 per cent of the activity. The lability to freeze-drying became more pronounced on further purification. Thus, after passage of the FSH fraction from DEAE-'Sephadex' through 'Sephadex *G*-100' the FSH fraction remained completely active after dialysis at 4° C for 20 h, but subsequent freeze-drying caused an overall loss of 68 per cent. Freeze-drying without dialysis caused a 45 per cent loss of activity while after storage in solution at 4° C for 14 days about 78 per cent of the original activity was retained. Quantitative recovery of FSH activity in *CP* 1 and other fractions could be obtained by concentration at 4° C of the solutions in dialysis tubing under reduced pressure.

This lability of FSH has previously been noted[2–4]. The extreme lability of purified FSH suggested to us that protective proteins were being removed during fractionation and prompted us to look for the presence of albumin which is known to protect many enzymes from loss of activity during freeze-drying. Investigation showed that on a DEAE-'Sephadex' column, albumin, detected immunologically by the haemagglutination method, was

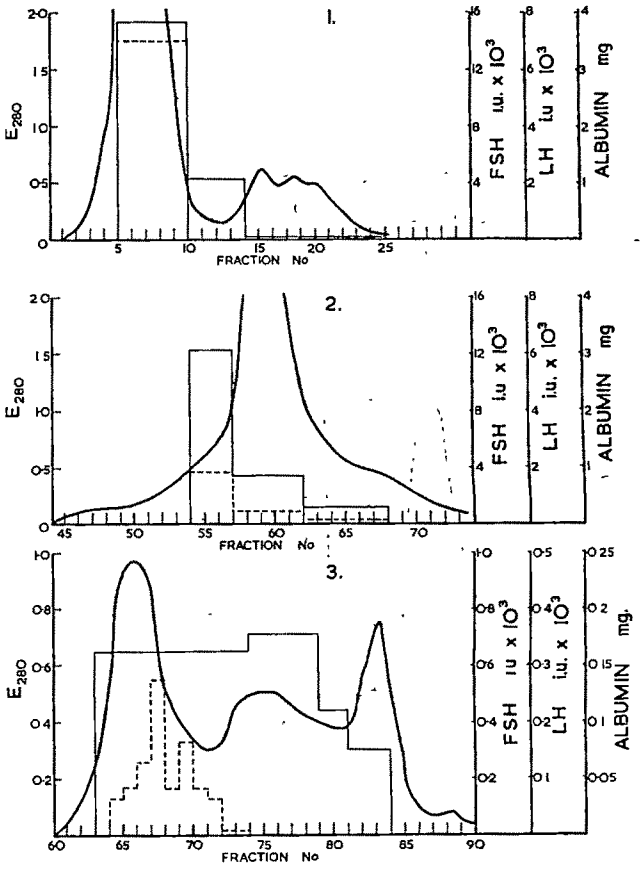

Fig. 1. Scheme for the purification of human FSH. Fraction *CP* 1 is passed down a column of 'Biogel *P*-150' (1) and FSH, LH and albumin are eluted mainly in fraction 5–9. This fraction is now applied to DEAE-'Sephadex' (2) and the eluate collected from fractions 57–61 is finally refractionated on a second column of DEAE-'Sephadex' (3). The FSH activity is eluted slowly over about twenty fractions, fractions 74–78 being virtually free of LH and albumin. ———, FSH; – – – –, LH; · · · · ·, albumin

indeed being removed since it was eluted after the major FSH fraction.

Our recommended procedure for preparing FSH free from LH and albumin is, therefore, an initial fractionation of *CP* 1 on 'Sephadex *G*-100' to remove inactive protein and subsequent fractionation and refractionation on DEAE-'Sephadex'. Recent work suggests that 'Biogel-150' may replace 'Sephadex *G*-100'. Two passages down DEAE-'Sephadex' are generally required to obtain the desired product. The latter columns particularly require to be closely scanned since the precise location of LH, FSH and albumin and the major ultra-violet absorption peak are somewhat variable, presumably due to formation of complexes between the various components. Recovery of activity on the columns as described here was 70–83 per cent.

A typical fractionation is shown in Fig. 1. Specific biological assays for FSH and LH demonstrated that the final product contained the equivalent of 1,000 (with 95 per cent fiducial limits of 730–1,430) mg first I.R.P.-human menopausal gonadotrophin (HMG) per ml. as FSH and less than 20 mg first I.R.P.-HMG per ml. as LH. (These results in I.U. are 143 (104–204) I.U. as FSH and <10 I.U. as LH.)

Purified FSH showed no loss of activity when compared with a control after incubation at 4° C for 2 weeks in 0·05 M cysteine, 0·05 M mercaptoethanol and 0·5 per cent serum albumin. Treatment with 0·05 M sodium nitrite in acetate buffer *p*H 5·0 for 43 h at 4° C caused 85 per cent loss of FSH activity, 64 per cent of which was recoverable after dialysis against 0·1 M mercaptoethanol (35 vol.) for 20 h, indicative of oxidation of –SH to –S–S– by sodium nitrite and reduction back to the original –SH groups by mercaptoethanol. Equal portions of FSH which had been dialysed for 24 h at 4° C against 8 M urea in acetate buffer *p*H 5·0 retained 50 per cent of the original activity, but this was completely lost by alkylation of the free SH groups with iodoacetamide (3·3 per cent; *p*H 7·0) for 4 h at 4° C. Treatment of FSH in formic acid (90 per cent; 1 ml.) at $-10°$ C for 2·5 h with performic acid (0·5 ml.) prepared from a mixture of formic acid (90 per cent; 9·5 ml.) and hydrogen peroxide (30 per cent w/v; 0·5 ml.) caused complete loss of activity, but some 50 per cent of the activity was lost on treatment with formic acid (90 per cent) alone at $-10°$ C for 5 h. FSH activity was found to be labile to acid and treatment with 0·2 M citrate buffer (*p*H 2·2) at 37° C for 25 h or with 0·05 M ascorbic acid (*p*H 2·0) at 4° C for 2 weeks caused complete loss of activity. This is probably associated with the cleavage of *N*-acetylneuraminic acid residues since treatment of FSH with *Vibrio cholerae* neuraminidase at *p*H 5·6 at 37° C for 2 h also caused complete loss of activity. No loss of activity was encountered on treatment of FSH with chymotrypsin at 37° C for 13 or 24 h in 0·2 M phosphate buffer (*p*H 7·0) and attack by trypsin was relatively slow. No loss of activity was encountered at 3–4 h incubation but after 16 h only 15 per cent activity remained. Using five times the concentration of trypsin some 50–60 per cent activity still remained after 8 h, but there was complete loss after 25 h. Pronase caused complete loss of activity after only 2 h incubation at *p*H 7·0 and 34° C and was by far the most destructive of the proteolytic enzymes tested.

We thank Dr. A. Stockell Hartree of the Department of Biochemistry, Cambridge University, for the supply of *CM* 1 fraction from the Medical Research Council collection of human pituitary glands. This work was supported by a block grant from the Medical Research Council.

REGIONAL LOCALIZATION OF LYSERGIC ACID DIETHYLAMIDE IN MONKEY BRAIN

By DR. SOLOMON H. SNYDER* and MARTIN REIVICH
Laboratory of Clinical Science, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland

THE hallucinogenic agent, *d*-lysergic acid diethylamide (LSD), profoundly alters integrative aspects of perception. Emotional functioning is also markedly affected and there is considerable evidence of central sympathetic discharge. On the other hand, the discrimination of primary modalities of sensation including touch, posture and kinaesthesia is not disturbed nor is voluntary movement impaired[1].

Neurophysiological investigations have revealed an impaired function in local regions of the brain after LSD administration. Thus, there is a highly specific depression of synaptic transmission in the lateral geniculate body of the cat[2]. In human subjects with subcortically implanted electrodes, LSD causes increased activation in the limbic system which is not present in simultaneously recorded neocortical leads[3].

The characteristic effects of LSD in man are produced after minute doses (less than 1 μg/kg) and persist for 8–12 h. Recently, it has been shown that after the administration of 2 μg/kg LSD intravenously to human subjects, the drug disappears slowly from plasma with a half-life of 3 h, and measurable quantities persist for 8 h (ref. 4). Moreover, there is an excellent correlation between the rate of disappearance of LSD from the plasma and the recovery of a normal performance on a simple arithmetic test. It would thus appear that impairment of mental functioning may be related to a continued presence of the unchanged drug.

In the present investigation we have examined the hypothesis that the effects of LSD on specific areas of mental functioning might be related to a capacity of the drug to selectively concentrate in specific regions of the brain. The regional localization of LSD in the brain of the squirrel monkey has been studied using a sensitive and specific fluorometric method for the measurement of unchanged LSD. The subcellular localization of LSD in several areas of the brain has also been examined.

Four adult squirrel monkeys (*Saimiri sciureus*) were used in these investigations. In one animal, which received 2 mg/kg LSD, the sub-cellular distribution of LSD in various regions of the brain was determined, while in the other three, which respectively received 2, 1 and 0·5 mg/kg of LSD, the regional distribution of LSD in the brain was investigated. LSD (Sandoz) was administered to the conscious animal by a slow intravenous injection over a 10-min period. The dose for each monkey was dissolved in 0·6 ml. saline. Twenty minutes after the end of the infusion the animal was killed by an intracardiac injection of air. The brain was perfused *in situ* with 250 ml. saline by way of the ascending aorta in order to remove as much blood as possible from the brain tissue. The brain was then removed and frozen

* Present address: Henry Phipps Psychiatric Clinic, Johns Hopkins Hospital, Baltimore, Maryland.

at −25° C in an acetone–dry ice mixture after which it was cut coronally into 3-mm sections using a brain macrotome. Using the atlas of Gergen and MacLean[5], each section was dissected into discrete regions which were kept in ice until analysed.

The LSD content of the dissected areas of brain was determined by the spectrophotofluorometric technique of Axelrod *et al.*[6], which is specific for LSD. As little as 0·001 μg per ml. of LSD can be measured by this method. The mean difference of duplicate determinations was 7·8 ± 2·4 per cent of the values.

The subcellular localization of LSD in various areas of the brain was examined by a method which will be described in detail elsewhere[7]. Tissues were gently homogenized in 10 ml. 0·25 M sucrose with a 'Teflon' pestle. The homogenate was centrifuged at 53,000*g* for 1 h in a discontinuous sucrose gradient prepared by successively placing into a *SW* 25 lusteroid tube 10 ml. 1·17 M sucrose, 10 ml. 0·73 M sucrose, and 10 ml. of the brain homogenate. In this technique the pinched-off nerve endings (synaptosomes) and mitochondria are located at the interface of the 1·17 M and 0·73 M sucrose layers, and the microsomal–myelin layer appears at the interface of the 0·25 M and 0·73 M sucrose layers. These layers, as well as the supernatant fluid, were removed with a Pasteur pipette and assayed for LSD content.

LSD was unequally distributed in the different areas of the brain (Table 1). The highest concentrations of the drug were found in the pituitary and pineal glands. These concentrations were 7–8 times the amount found in the cortex. The anterior pituitary had approximately twice the concentration found in the posterior pituitary gland. Structures of the limbic system, that is, the hippocampus, amygdala, fornix, and septal region, contained 2–3 times the cortical concentration of LSD. Among the deep cerebral structures LSD was 2–5 times more concentrated in the visual and auditory areas and hypothalamus than in the cortex. The extrapyramidal system and thalamus contained approximately 1·5 times the cortical concentration. Among the superficial cerebral structures LSD was about equally distributed between white and grey matter. LSD was not notably concentrated in the visual cortex. The brain stem contained concentrations of LSD similar to that found in the cortex. In one experiment the blood concentration of LSD was determined just prior to killing the animal and was found to be the same as the cortical concentration. The cerebellum contained significantly less LSD than the cerebral cortex. In one animal the concentration of LSD in the iris was measured and found to be 18 times as high as that of the cortex.

Table 3. Subcellular Distribution of LSD in Monkey Brain
Percentage of total LSD in subcellular fractions

	Supernatant	Microsomes-myelin	Synaptosomes-mitochondria
Hippocampus	75	20	5
Frontal grey	73	19	8
Frontal white	77	20	3
LSD added to homogenate	79	15	6

Sub-cellular fractions of the hippocampus, frontal grey matter, and frontal white matter were prepared as already described. In a separate experiment, LSD was added at 4° C to an intact brain, which was then homogenized and carried through the previously described isolation procedure. In the areas of the brain examined, LSD was largely confined to the soluble supernatant fluid (Table 3). The sub-cellular localization was the same when LSD was added to the homogenate. These results would indicate that LSD does not localize in a specific subcellular brain particle.

After intravenous administration of LSD, the drug is unequally distributed in the different areas of the brain of the monkey, with about a ten-fold variation between structures with the highest and lowest concentrations. These differences in concentration are probably not due to differences in regional blood flow to these areas since these investigations were performed 30 min after the start of the infusion. Although the initial distribution of LSD in the brain would be determined by the regional cerebral blood flow, after 30 min it might be expected that the various tissues would be approaching equilibrium with the blood levels of LSD and regional blood flow would no longer be the determining factor. This is supported by the fact that a comparison of regional blood flow values[8] and LSD concentration shows no significant correlation ($r = -0·03$; $P > 0·9$).

It is also unlikely that the unequal distribution of LSD is simply the result of its lipid solubility and consequent predilection for white matter. There was no apparent difference in the LSD content of cerebral cortex and white matter. Furthermore, LSD was highly concentrated in structures which are not especially rich in white matter such as the pituitary and hypothalamus.

Another factor which should be considered is the vascularity of different regions of the brain. However, since the maximum vascularity in the brain[9] is of the order of 3 per cent and since the blood concentration of LSD was the same as that in the cortex, the different blood content of various regions of the brain could not account for the

magnitude of the differences in regional LSD concentration found. Furthermore, attempts were made to wash the blood from the brain before the determinations were made.

In an investigation of the regional distribution of mescaline-^{14}C in the cat brain, Neff *et al.*[10] found that mescaline, like LSD, was present in high concentration in the pituitary and lateral and medial geniculate bodies. In contrast to the present results with LSD, high concentrations of mescaline were found after 30 min in the cerebrocortical grey matter while white matter contained only 25 per cent as much mescaline.

Arnold *et al.*[11] investigated the distribution of ^{14}C-LSD in the mouse brain by an autoradiographic technique. They also divided the brain into cerebrum, brain stem, medulla, and cerebellum, and determined the total radioactivity in these regions. It was found that cellular areas had higher activity than white matter and that these areas could be arranged in order of decreasing activity as follows: limbic lobe, hippocampus, basal ganglia, grey matter around the third ventricle, cerebral cortex and cerebellum. As the authors point out, these studies do not distinguish between LSD and its metabolites. However, in the regions they analysed, the order of decreasing activity is essentially the same as found in the present investigation.

LSD produces marked perceptual distortions. These effects appear to be the result of affectively determined perceptual alterations and hallucinations. There is, however, no marked impairment of discrimination of the primary modalities of sensation[1]. In the present investigation, there was no particular localization of LSD in the primary sensory areas of the cerebral cortex. The drug, however, was highly concentrated in subcortical visual centres, which have been implicated in the production of visual hallucinations[12]. LSD was also found in high concentrations in the limbic system and in the hypothalamus, areas which are thought to be involved in the mediation of affective behaviour[13]. Monroe *et al.*[3] found that the most significant response to LSD was the appearance of subcortical paroxysmal activity, which was most often limited to the septal, anterior hypothalamic, or amygdaloid-hippocampal regions. Dramatic behavioural changes were usually associated with the electroencephalographic changes in these areas. Certain mental effects of LSD have previously been shown to be related to persistent plasma levels of unchanged LSD[4]. It is possible that some of the effects of LSD on 'emotionality' and affectively determined perceptual alterations might be related to the selective concentration of this drug in areas thought to be involved in these functions.

LSD produces central sympathetic stimulation with effects which include hyperglycemia, mydriasis, pilo-erection, tachycardia, leucocytosis, and a rise in body temperature. These effects are related to the stimulation of mesencephalic and diencephalic structures[14], areas which selectively concentrate LSD.

The above evidence is merely suggestive and obviously no conclusions can be drawn from this investigation as to the mode of action of LSD in producing its characteristic effects. Furthermore, in order to obtain adequate tissue levels for fluorometric assay relatively high doses of LSD were administered in the present study. It is possible that with smaller doses the relative concentration of LSD in those areas which we found had high concentrations might be more pronounced.

In the investigations of subcellular distribution, the localization of LSD in the cell sap would suggest that LSD is not bound to subcellular particles. Arnold *et al.*[11], on the basis of their autoradiographic investigations, concluded that the activity was present in the cytoplasm and not in the nucleus.

INCREASED RED CELL BREAKDOWN IN ADOPTIVELY IMMUNIZED YOUNG *NZB* MICE

By Dr. R. D. S. BARNES and MAUREEN TUFFREY

Department of Haematology, Institute of Child Health, Hospital for Sick Children, Great Ormond Street, London

MICE of the *NZB* strain spontaneously develop haemolytic anaemia with autoantibodies against red cells[1]. Holmes, Gorrie and Burnet have described a positive direct Coombs's test (D.C.T.) in such mice, and have been able to detect this antibody in young mice adoptively immunized with spleen cells from older D.C.T. positive animals[2]. We recently described an antihuman red cell cross-reacting antibody (A.H.R.) in these mice[3], and now, using the spleen cell adoptive immunization technique, have been able to induce this antibody in young animals. Using red cells labelled with chromium-51, we have tried to relate the presence of these two antibodies to increased red cell breakdown which, in man, is an essential feature of autoimmune haemolytic anaemia.

Animals. The *NZB* mice were part of the colony kept in conventional animal housing at Taplow. Donors were selected on the basis of sex and their antibody status. Recipients, 4–6 weeks of age, were separated into three groups prior to the injection of spleen cells (Table 1): those receiving spleen cells from donors which were (*A*) A.H.R. + D.C.T. +, (*B*) A.H.R. − D.C.T. +, (*C*) A.H.R. − D.C.T. −. Each group contained both males and females, individual mice receiving cells from a donor of the same sex.

Spleen cell suspensions. In each group different numbers of donor animals were killed and their spleens taken after perfusion with saline. Spleen cell suspensions were prepared by gentle homogenization of individual spleens in a

Table 1. Groups of Young *NZB* Mice Receiving Spleen Cells from *NZB* Donors

Group	Donor antibody status	No. of recipients Male	Female
A	D.C.T. + A.H.R. +	14	8
B	D.C.T. + A.H.R. −	6	15
C	D.C.T. − A.H.R. −	12	11

D.C.T., direct Coombs's test (+ or −).
A.H.R., antibody against human red cell antigen present in serum (+ or −).

Potter mill and the number of viable cells in each spleen cell suspension was counted in trypan blue. The suspensions were adjusted to contain 33–37 × 10^6 viable cells per 0·1 ml. and inoculations of this amount were given intraperitoneally to the recipients. Female recipients of Group *B* all received cells from one considerably enlarged donor spleen. Group *C* recipients received cells pooled from more than one donor spleen.

Radiochromium red cell investigation. Red cells from normal young *NZB* were labelled with chromium-51 according to the method of Dacie and Lewis[4] using 5 μc. of $Na_2{}^{51}CrO_4$ per ml. of whole blood.

0·2 ml. of a labelled 50 per cent red cell suspension was injected intravenously into each recipient 8 days after the introduction of spleen cells. This interval was allowed since preliminary tests suggested that the likelihood of detecting autoantibodies in recipients was greater after 7 days. Pairs of recipients were killed at successive intervals (usually 2–3 days) between 10 and 36 days after injection of spleen cells.

Whole-body total radiation counts were performed after injection of the labelled cell suspension using a large well counter similar to that described by Warner and Oliver[5], but using a plastic scintillator giving a capacity of 13 × 14 cm with a 7-in. photomultiplier. This well was used in conjunction with an 'Echo' pulse height discriminator and scaler. 0·2 ml. of the original labelled cell suspension haemolysed with distilled water was counted and considered as a standard dose.

Blood radiochromium counts in recipient mice were estimated on 0·2 ml. blood which was haemolysed after withdrawal by cardiac puncture on the day of killing. Counts were performed in a standard 'Panax *LC*4' small well in conjunction with an 'Echo' scaler.

It was assumed that the whole-body radiation count immediately after the injection of labelled red cells was representative of the dose given. In order to compare the blood counts of individual animals, we thought it necessary to correct the counts to a unit dose, by using the formula:

$$\text{Corrected blood count} = \frac{\text{standard dose count}}{\text{whole body count}} \times \text{blood count}$$

Counts were also corrected to unit packed cell volume.

Haematological and antibody evaluation. Haematological values were determined according to the methods of Dacie and Lewis[4] and were limited to the estimation of haemoglobin, packed cell volume and reticulocyte count.

Antibody tests were performed on all the donors before and after they were killed, and on all the recipients on the day they were killed. Direct Coombs's tests were performed on the red cells, and the sera were examined for A.H.R. activity by the immunofluorescent method previously described[3], in which red cells present in the capillaries of human neonatal thyroid provide the substrate.

Occurrence of antibodies. The antibody status of the donors was confirmed in each case before killing. The presence of antibodies in the sera of the individual recipients at the time of killing them is recorded in Table 2. The uniformly negative results obtained in group *C* show that autoantibodies did not develop spontaneously in the recipients during the period of the experiment.

In group *B* the occurrence of a positive D.C.T. was observed in both sexes and in a total of fifteen out of twenty-one recipients. One out of six males and fourteen out of fifteen females were positive. In no animal of either sex in this group was A.H.R. antibody detected.

In group *A* the occurrence of A.H.R. antibody and of a positive D.C.T. test was observed in both males and females. A.H.R. antibody was found in three of eleven males tested, and in three of eight females. The D.C.T. test was positive in most of the mice in this group, but one animal (a male killed on day 22) had a negative D.C.T. although A.H.R. antibody was detected in its serum.

It must be pointed out that these antibody results represent findings on the day on which the individual mice were killed and do not necessarily represent the antibody status for the preceding period.

Blood radioactivity counts. Individual blood radioactivity results obtained are presented in Fig. 1 after correction to unit dose and packed cell volume.

Group *C* males and females gave results suggesting a steady decrease in blood radioactivity over the period of the experiment. It might be anticipated from the individual results in this group that at least some of the injected chromium-labelled red cells normally survive in the blood for as long as 40–50 days.

In group *B* the females show lower levels of blood radioactivity than the controls in group *C*. In one female, red cell survival was less than 20 days. The males show little or no difference from group *C* animals; it must be remembered that in only one male was a positive D.C.T. recorded.

In group *A* animals, both male and female blood radioactivity counts were markedly less than group *C*. With few exceptions, lower levels were found in mice of this group than in either of the other groups. In two mice in group *A* red cell survival appeared to be less than 15 days.

Haematological values. The reticulocyte counts, packed cell volumes and haemoglobin values are shown in Fig. 2.

Within each sex, and for haemoglobin and reticulocyte counts separately, a comparison of groups *A*, *B* and *C* was made, ignoring time, in a one-way analysis of variance design. Since comparison of pairs of groups was also of interest, for example group *A* with group *B*, these comparisons were made in such a way as to ensure that the chance of accepting a difference between two identical means for the three comparisons was not greater than the nominal significance level (5 per cent or 1 per cent)[7]. The results are set out in Table 3, which shows that, ignoring time, there are statistically significant group differences in haemoglobin and reticulocyte values between groups *A* and *C*, and *A* and *B*.

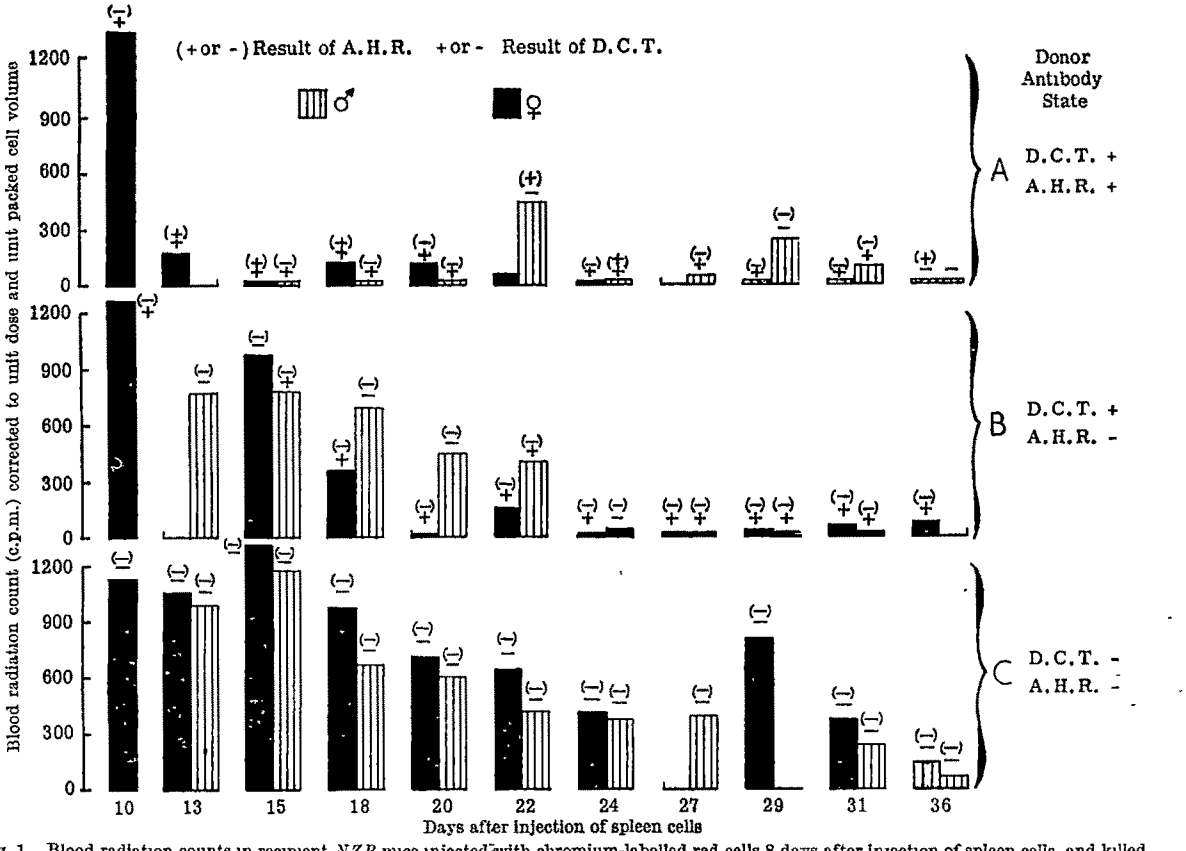

Fig. 1. Blood radiation counts in recipient *NZB* mice injected with chromium-labelled red cells 8 days after injection of spleen cells, and killed 10–36 days thereafter

In man, autoimmune haemolytic anaemia is characterized by an increased *in vivo* red cell destruction associated with the presence of an autoantibody against the red cell. In the *NZB* mice the spontaneous occurrence of anaemia and various red cell autoantibodies have been described[1,2]. We present evidence here to suggest that the anaemia in these mice, like the disease in man, is associated with increased red cell destruction. We have also related the red cell destruction pattern to induction of the two autoantibodies already defined.

Adoptive immunization of *NZB* mice was first performed by Holmes *et al.*[2]. Injecting spleen cell suspensions from old D.C.T. positive *NZB* donors, they were able to transmit the ability to produce a positive D.C.T. to younger animals of the same strain. We have also succeeded in transferring the ability to develop a positive D.C.T. by means of spleen cell suspensions. In addition, we have been able to detect A.H.R. antibody in a group of recipients injected with spleen cells from A.H.R. +, D.C.T. + donors. In this type of transfer experiment it is necessary to establish that any antibody production in recipients is not due to activation of their own immune systems. In control group *C*, neither a positive D.C.T. nor A.H.R. antibody was detected. This shows the absence, in young animals of the age of recipients, of either spontaneous autoantibody production or induction of antibody by injecting spleen-cells from negative donors.

Donor Antibody Status: *A* {D.C.T. +, A.H.R. +} *B* {D.C.T. +, A.H.R. −} *C* {D.C.T. −, A.H.R. −}

In group *B*, it is apparent that the majority of female recipients, receiving spleen cells derived from one female donor, had succeeded in acquiring a positive D.C.T. This contrasted with the males in this group, in which a positive D.C.T. was recorded in only one instance. It is possible that this was due to technical failure in transmission of spleen cells, but as three separate spleen cell suspensions from three different donors were used this seems unlikely.

In group *A*, unlike groups *B* and *C*, we were successful in inducing formation of A.H.R. antibody in both males and females. As can be seen from Table 2, the positive A.H.R. results were obtained only between day 13 and day 24 after cell transfer, whereas the positive D.C.T. results ranged over the whole experimental period. We were particularly interested to note the relatively short duration of these antibody responses; in experiments not described here we have noted also the eventual disappearance of the adoptively transferred positive D.C.T. response, as described by Holmes *et al.*[2]. The transient character of the adoptive immunity investigated here might be due to lack of appropriate antigen, or other stimulus, in the young *NZB* hosts, or might indicate rejection of the spleen cell graft occurring despite the inbred character of the *NZB* strain. Experiments are at present being performed to investigate these adoptive immune responses in irradiated recipients.

The blood chromium levels were determined on only a few mice at each time interval after injection of labelled red cells. However, the results showed definite differences between the groups. In the control group it could be seen that the labelled red cell survival was likely to exceed 40–50 days. The group *B* females showed levels indicating a moderate decrease in labelled red cell survival, although the males in this group showed no difference from the controls, as might be expected from their mainly negative D.C.T. results. The group *A* animals gave individual blood radioactivity counts markedly lower than those

recorded in the control group. In several instances, results showed that mice in group *A* had greatly decreased red cell survival, even when compared with group *B*.

The haematological evaluation is also consistent with this view that the process induced in most of the group *A* mice is an acute haemolytic episode, and confirms the acuteness and severity indicated by the radiochromium results. The spectacular fall in blood chromium levels and rise in the numbers of reticulocytes in the peripheral blood would suggest a considerable rate of red cell breakdown in group *A*. Surprisingly, the fall in haemoglobin is not so marked and is presumably influenced by the extent of red cell compensation. Looking at results in individual animals, it is apparent that certain females in group *B*

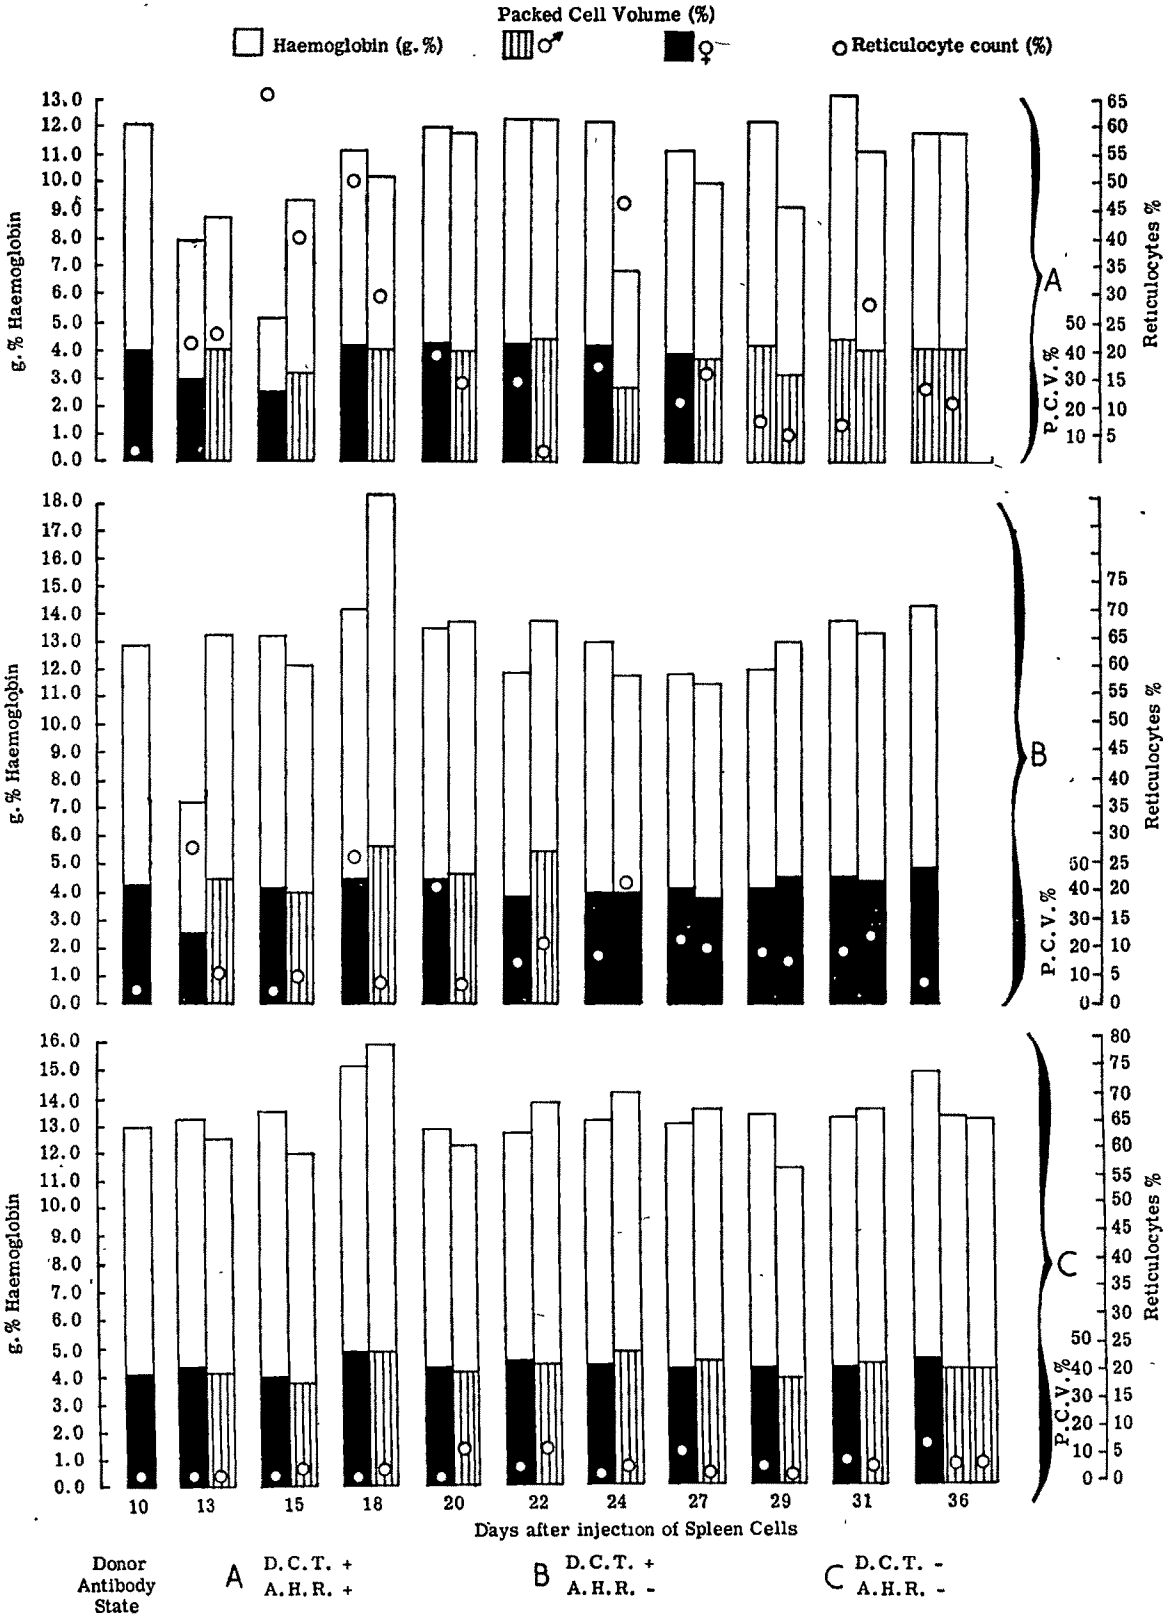

Fig. 2. Haematological values in adoptively immunized *NZB* mice

are anaemic and have a reticulocytosis when compared with group *C*. However, in the group analysis independent of time, group *A* was the only group to show statistically significant degrees of anaemia and reticulocytosis. These results suggest that if the *NZB* donors of spleen cells used to immunize young *NZB* mice adoptively are both D.C.T.-positive and already producing A.H.R. antibody, red cell destruction in the recipients is significantly greater than when donors are positive only by D.C.T. It seems likely, therefore, that the A.H.R. antibody itself enhances red cell destruction. It is also possible, however, the A.H.R. antibody is produced as a result of red cell destruction—which might, for example, reveal hidden antigenic determinants on the red cell surface—but this is perhaps less likely in view of the absence of A.H.R. antibody in group *B* recipients.

Helyer and Howie[6], in describing the spontaneous anaemia associated with the *NZB* mice, noticed the tendency of the males to develop anaemia earlier than the females. The spontaneously occurring A.H.R. antibody appears earlier and also more frequently in males, and we suggest that the earlier and more severe anaemia seen in the spontaneous disease in males[8] is related to this.

Further investigation of red cells, labelled with chromium-51, to estimate the actual half-life of the red cells in the spontaneous disease process are being performed.

We thank Mr. H. Goldstein, lecturer in statistics, Institute of Child Health, for his advice, and Miss Jean Holliday for technical assistance. We thank Mr. G. Lythe for the illustrations.

AND

Dr. ELIZABETH M. TUCKER

Agricultural Research Council Institute of Animal Physiology, Babraham, Cambridge

TWO allelic adult haemoglobins A and B are found in sheep as well as foetal haemoglobin F[1,2]. When sheep with haemoglobin A are made anaemic by bleeding, the proportion of haemoglobin A falls and another haemoglobin appears (Fig. 1)[3]. Blunt and Evans[4] suggested that this might be a new haemoglobin and van Vliet and Huisman called it haemoglobin C (ref. 5). When bleeding is stopped haemoglobin C gradually disappears and haemoglobin A returns to its former proportion. When sheep with both haemoglobin A and B are bled, only the proportion of haemoglobin A falls on the appearance of haemoglobin C. Sheep with haemoglobin B only, produce no haemoglobin C on bleeding[5,6]. Replacement of one haemoglobin by another under environmental stress is a unique phenomenon, and we have been investigating the relationship between haemoglobin C and the other sheep (or ovine) haemoglobins.

As a first step each of the four haemoglobins was isolated by repeated paper electrophoresis and dissociated into its sub-units at *p*H 4·6 in the presence of human and canine haemoglobin respectively[7,8]. After reassociation, the sub-units formed no hybrid haemoglobins with the sub-units of human haemoglobin. Hybridization with canine haemoglobin resulted in two hybrids, $\alpha_2^{can}\,\beta_2^{ov}$ and $\alpha_2^{ov}\,\beta_2^{can}$, of which the second moved more slowly than the first towards the anode on electrophoresis at *p*H 8·6 (Fig. 2). The $\alpha_2^{ov}\,\beta_2^{can}$ hybrid had the same electrophoretic mobility whether ovine A, B, C or F had been used for hybridization; but the hybrids of the canine α-chain with the non-α-chain of each of the four ovine haemoglobins differed in their mobilities. This suggested that the α-chains of the four ovine haemoglobins were similar and that the differences between these haemoglobins rested in their non-α-chains. This result has been reported independently by van Vliet and Huisman[5]. We will denote the non-α-chains of the ovine haemoglobins A, B, C and F as β^{ovA}, β^{ovB} β^{ovC} and γ^{vF}.

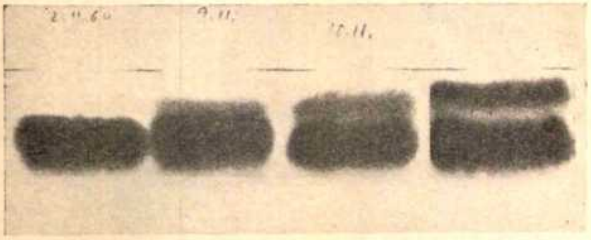

Fig. 1. Appearance of haemoglobin C in increasing proportion after bleeding a sheep with haemoglobin A. The course of bleeding consisted of removing about 2 l. of blood over 4 days. The electrophoretograms represent from left to right the haemoglobin composition on day 1, 7, 8 and 10

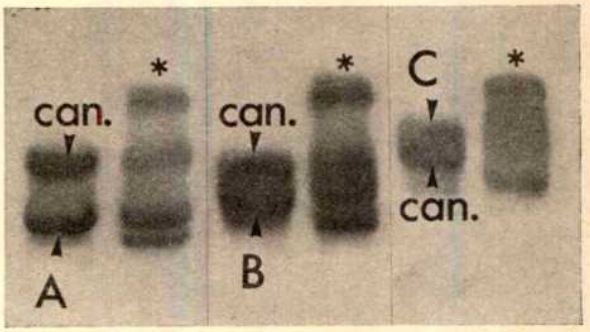

Fig. 2. Hybridization of sheep haemoglobins A, B, and C with canine haemoglobin. From left to right: mixtures of Hb A, B, C, respectively, both before and after dissociation and recombination. The '*' indicates the $\alpha_2^{ov}\,\beta_2^{can}$ hybrid which has the same mobility whether the α_2^{ov} is derived from the ovine Haemoglobin A, B, or C. This suggests that the different mobilities of these three sheep haemoglobins are based on differences in their non-α-chains. (See also van Vliet and Huisman[5].)

Information about the primary structure of the ovine haemoglobins was then obtained by studying their tryptic peptides. Globin was prepared using acid acetone, and

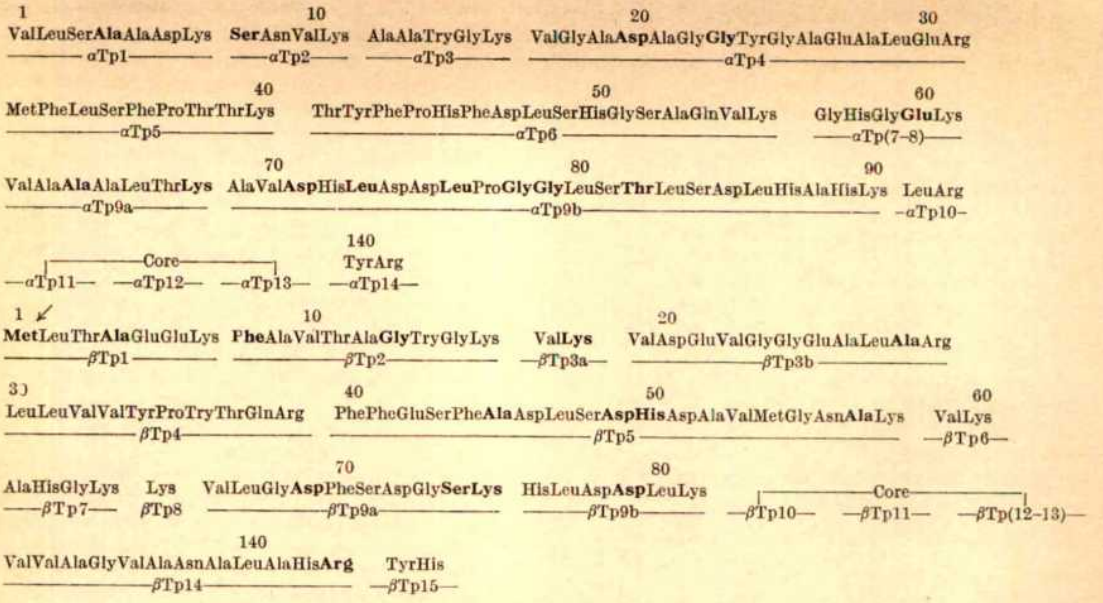

Fig. 3. Most probable partial sequences of the α- and β-chains of ovine haemoglobin A
Bold type indicates the most probable positions of the amino-acid residues which differ in ovine haemoglobin A and in human haemoglobin A. Arrow shows position where a deletion has probably occurred in the evolution of the β^{OVA} chain

digested with trypsin. The peptides that were soluble at *p*H 6·4 were separated from those in the insoluble 'core', and then submitted to paper electrophoresis[9] and chromatography[10]. Those from ovine haemoglobin A were analysed on an automatic analyser[11]. Details of the methods used have recently been summarized[12]. By comparing the amino-acid compositions of the ovine A peptides with those from human haemoglobin A[13,14], it was possible to put the ovine peptides into sequential order and also to infer the most likely sequence of amino-acids within each peptide. The tentative partial sequence is shown in Fig. 3. In a few cases the amino-acid composition of the peptide was not exactly reproducible and further investigation may necessitate minor alterations in the proposed sequences for αTp9b and βTp5.

Peptide maps of ovine haemoglobins A, B, C and F (Figs. 4–7) revealed no differences in the α-chain peptides but several non α-chain differences were apparent. The B peptide map (Fig. 5) differs from that of A (Fig. 4) as follows: An arginine peptide is missing (1). There are two new methionine peptides (2) which are probably structurally related. βTp5 has a lower R_F (3). There is an additional acidic peptide (4). Except for the first difference these results can be correlated with those of Muller[15].

The F peptide map (Fig. 6) differs from that of A (Fig. 4) as follows: There is an additional arginine spot (5), which is probably free arginine. The tryptophan peptide β2 found in haemoglobins A and B is missing but there is an additional peptide nearby which does not contain tryptophan (6). There is a faint additional basic peptide (7)

and an additional neutral peptide (8). The peptide in the position of γTp5 does not contain methionine (9). There is an additional acidic peptide (10). Peptide maps of foetal haemoglobin from new-born sheep with haemoglobin A and with haemoglobin B were identical.

The C peptide map (Fig. 7) differs from that of A (Fig. 4) as follows: There is an additional arginine positive spot (11) which is probably free arginine. There are two additional basic peptides (12, 13) and an additional neutral peptide (15). The tryptophan peptide β2 is missing, but there is an additional peptide nearby which does not contain trytophan (14). The peptide in the position of βTp5 does not contain methionine (16). The peptide in the

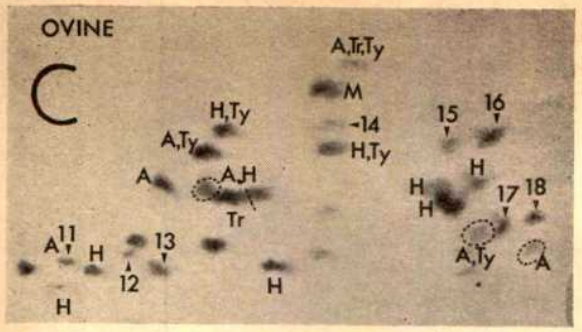

Fig. 7. Peptide map of ovine haemoglobin C. Details as in Fig. 5

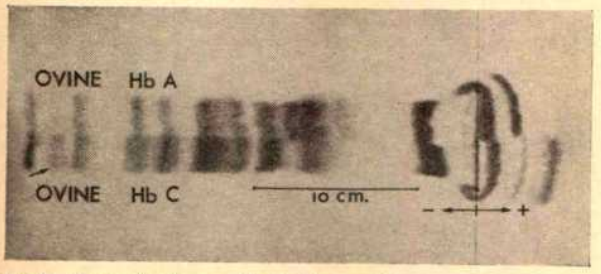

Fig. 8. Electrophoretogram of ovine haemoglobins A and C. The arrow indicates the area staining for arginine, which is absent in A but present in C

position of βTp1 does not contain methionine (17) and there is an additional acidic peptide (18).

The additional arginine positive spot (11) was used to detect small amounts of haemoglobin C in sheep with haemoglobin A in the absence of haemoglobin F. An extended electrophoretogram shows this more clearly (Fig. 8).

Of 94 residues accounted for in the ovine α-chain at least thirteen differ from those of the human α-chain. Assuming that the two chains have the same length (141 residues) there are likely to be at least twenty differences in amino-acid sequence. Ninety-five residues have been accounted for in the β^{ovA} chain of which at least fifteen differ from those of the human β-chain. If this ovine chain is assumed to have one residue less than the human β-chain (145 instead of 146) due to a deletion at position two, one might expect a total of at least twenty-three differences. These differences are what one would expect from the assumption that man and sheep diverged about 100 million years ago and that a mutation giving rise to a change in amino-acid sequence occurs every 8–10 million years[16].

Only seven amino-acid residues could be found in the first tryptic peptide of the β^{ovA} chain whereas there are eight in the equivalent peptide from man. Of the mammalian haemoglobins so far investigated this difference has only been found before in cattle haemoglobin[17]. The N-terminal residue of the ovine peptide was found to be methionine by a modified dinitrophenyl method[18], and this residue is the same as that reported for the N-terminal of the β^{ovA} chain[19]. Digestion of the peptide with chymotrypsin resulted in two products which were found to have the amino-acid compositions Met, Leu and Thr, Ala, Glu_2, Lys respectively. The latter had an N-terminal threonyl so that the partial sequence Met–Leu–Thr–(Ala,Glu,Glu)–Lys can be assumed for β^{ovA}Tp1.

It is believed that the human β-chain evolved from a primitive α-chain by way of the γ-chain by means of gene duplication[20]. During this process an extra residue was added at position two enhancing the molecular divergence of the chains.

N-terminal sequences of human α- and β-chains are:

α Val– Leu–Ser–Pro – –

β Val–His–Leu–Thr–Pro – –

It would appear, therefore, that a deletion has arisen in the ovine β-chain giving it an unexpected resemblance to the ovine α-chain (see Fig. 3). Such a deletion may be an example of evolutionary convergence operating at the molecular level.

The peptide maps of the ovine haemoglobins A and F suggest that there is a greater similarity between the β^{ovA} and γ^{ovF} chains than one might have expected. This was further emphasized by finding that the rather rare methionine residue was N-terminal in both. N-terminal methionyl has also been reported for the non-α-chains of adult and foetal cattle haemoglobin[17]. Zuckerkandl and Pauling[21] have suggested that the gene duplication which gave rise to these peptide-chains of cattle may have occurred considerably later in evolution than that which gave rise to the human β- and γ-chains. This may well apply also to the ovine chains.

Hybridization, amino-acid analysis[22] and peptide mapping have failed to reveal any differences between the α-chains of the four ovine haemoglobins. Therefore it can be assumed with reasonable confidence that these chains have identical amino-acid sequences. The β^{ovA} and β^{ovB} chains are closely related as might be expected for two alleles. Whereas the human allelic haemoglobins differ in one residue, in sheep there are several differences. This may be because the sheep is a much older mammal than man, or possibly sheep with haemoglobin A and haemoglobin B developed separately in different environments. The peptide maps of the two haemoglobins show differenees that might be due to changes in the peptides βTp5, βTp14 and one likely to arise from a core peptide. The β^{ovC} chain appears to differ more widely from both the β^{ovA} and β^{ovB} chains than these two differ from each other. The peptide maps show numerous differences which suggest changes in βTp1, βTp2, βTp5, βTp9, and in the core peptides. Although there is a greater resemblance between the β^{ovC} and γ^{ovF} chains, differences occur at least between β^{ovC}Tp1 and γ^{ovF}Tp1 as well as possibly in the core peptides. One important difference is that unlike the β^{ovA}-, β^{ovB}- and γ^{ovF}-chains the β^{ovC}-chain has no N-terminal methionyl.

Braend and Efremov[23] have found traces of a second haemoglobin in some apparently normal sheep with haemoglobin A. They suggest that this haemoglobin may be a normal rather than an abnormal component, and that a gene linkage may operate between the β^{ovA}- and β^{ovC}-chains similar to that which operates between the human β- and δ-chains. We have consistently found traces of haemoglobin C in all the thirty-one sheep of the Soay and Clan breeds with haemoglobin A or AB we have investigated, but we have never found haemoglobin C in a sheep with only haemoglobin B, even after severe bleeding. When on occasion haemoglobin C did not separate from haemoglobin A on first paper electrophoresis, the rear part of the A band was cut out, eluted, and the eluate after concentration was again submitted to electrophoresis. By this means sufficient haemoglobin C became available to separate from A on paper electrophoresis, and for high-voltage electrophoresis of the peptides to demonstrate the free arginine spot (11) (see Fig. 8).

It would appear, therefore, that the process by which haemoglobin C forms the major proportion of the haemoglobin in anaemic sheep with haemoglobin A is due to an increase in means of synthesis or rate of synthesis rather than to the switching on of a new gene. We have also observed that the rise in the level of haemoglobin C on bleeding coincides with the reticulocytosis. Possibly haemoglobin C is synthesized primarily by the reticulocytes whereas haemoglobin A is primarily synthesized by the normoblasts. This would represent a fundamental difference in the regulation of protein synthesis by the reticulocytes and the late normoblasts of the A sheep but not of the B sheep. It has been proposed that reticulocytes, in view of their difference from normoblasts in size[24] and in metabolism[25], are not part of the normal cell line, but appear under stress as a by-pass of the regular cell production by

way of the normoblasts. The observations in A sheep seem to lend support to this concept.

COMPARATIVE IMMUNOCHEMICAL PROPERTIES OF NUCLEOPROTEINS: ANTIGENIC CHARACTERISTICS OF DEOXYRIBONUCLEIC ACID PROTEIN FROM A CANINE HAEMANGIOPERICYTOMA

By Prof. R. H. WILSON*, V. JUREVICS, R. DELANEY, T. RITTER, K. RENCZ and A. SCHRAM

Veterans Administration Hospital, Research Department, Dallas, Texas

THE question of the comparative immunochemical properties of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), deoxyribonucleic acid protein (DNAP) and the simple alkaline proteins of nuclei, such as histones and protamines, has by no means been completely answered[1–4].

Plescia *et al.*[5] have reported the production of antibodies to *t*RNA. In this work methylated bovine serum albumin (MBSA) was used as an effective carrier for *t*RNA from the yeast cell. Complexes of RNA–MBSA were prepared by adding MBSA (10 mg/ml. water) to RNA (500 μg/ml. in 0·15 M sodium chloride) and injected, as an emulsion with complete Freund's adjuvant (CFA), into the foot pads and intramuscular routes in New Zealand white rabbits. The immune sera were reported to contain antibodies against yeast *t*RNA that cross-reacted with *Escherichia coli t*RNA and synthetic poly-uridine (poly-U). These antisera also reacted with partially purified alanyl *t*RNA and Worthington RNA. These antigens contained no detectable traces of amino-acids and sugars other than D-ribose. Thus, the antigenic determinants involved ribonucleotides presumably in sequence.

If an immunochemical model could be designed for the purpose of determining the characteristics of the sequence of the nucleotides in DNA and RNA, problems concerning the structure of the nucleic acids in different organs and in different species would be simplified.

Wilson *et al.*[1] reported that calf thymus DNA with a molecular weight of $9{\cdot}3 \times 10^6$ was neither antigenic nor haptenic in rabbits. Further studies by the same investigators using deoxyribonucleic acid-histone as an antigen in large quantities over a long period of time revealed that DNAP, free of proteins other than histones, was not antigenic in New Zealand white rabbits. Cross-reaction studies with the histones, DNA and DNAP, from the calf thymus showed that these materials are neither antigenic nor haptenic, in the reported experimental model. However, this does not mean that the DNAP from other sources, such as bacteria and viruses, lack antigenic and/or haptenic properties. It is also recognized that degraded DNA and/or DNAP may be weakly antigenic.

It was therefore thought to be important to the investigation of the comparative immunochemical properties of the nucleoproteins to include in the experimental model DNA, DNAP and histones from a canine cancer haemangiopericytoma.

A 12-year-old male English setter was admitted to the experimental animal quarters with a 37-cm² tumour on the lateral aspect of the left thorax and abdomen. This tumour was removed surgically three times within a period of 6 months. It was growing rapidly and an attempt to remove the entire tumour proved ineffective. The weight of the dog was 52 lb. at the time of its admission to the experimental animal quarters. The gross examination of the tumour revealed that it was subcutaneous, nodular and firm.

A section of the tumour was sent to the Texas A and M College, Department of Animal Pathology, where a diagnosis of haemangiopericytoma was made (Fig. 1). This tumour was described by Stout *et al.*[6] in man and by Mulligan[7] in 68 dogs. Histological examination revealed that it consisted in general of spindle-shaped cells with ovoid or elongated nuclei with considerable cytoplasm which was fibrillar in character. Within the tumour numerous small capillaries lined the endothelium which were closely encircled by the anaplastic and pleomorphic spindle cells; these were considered to be pericytes.

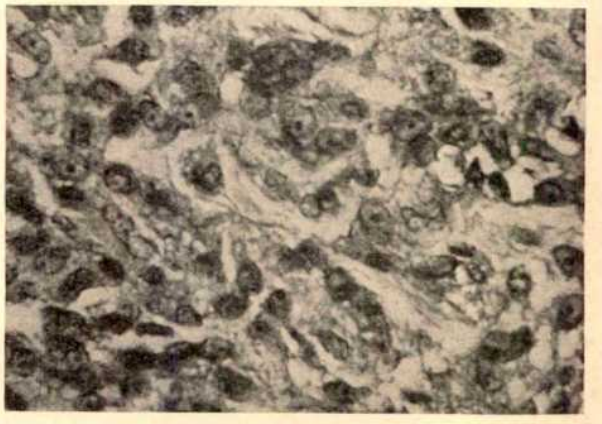

Fig. 1. Photomicrograph of a section of the haemangiopericytoma from which the DNAP was isolated for the immunochemical study

* Present address: University of North Dakota, Grand Forks, North Dakota.

The circulating eosinophil count was 250 at the beginning of the period of observation. The total leucocyte count was 7,500 and the differential count was 65 per cent polymorphonuclear leucocytes, 30 per cent lymphocytes and 5 per cent other types of leucocytes; the BUN was 1·5 mg per cent and the urine analysis was within normal limits.

The dog was anaesthetized by the injection of 20 ml. of sodium pentothal. The tumour was removed, immediately frozen and kept in the deep freeze at −40° C. The DNA was isolated from fresh frozen tumour using the method of Kay, Simmons and Dounce[8]. This method was carried out essentially as follows: the tumour was placed in a dry-ice container immediately after removal from the dog. It was then stored in a deep freeze at −40° C for 2 days. The tissue was thawed, and all gross fat portions removed. It was then cut into small pieces which were washed five times with 100-ml. portions of 0·1 M aqueous sodium citrate. The mixture was homogenized four times using 250-ml. 0·1 M citrate each time. In the first homogenate 1 ml. of octanol was added to prevent foaming. The homogenate was centrifuged at 1,800*g* for 30 min each time. The final residue was extracted with 1,000 ml. 2 M aqueous sodium chloride. The sodium chloride solution was added in increments until the viscosity of the preparation was that of a thick paste.

The mixture was placed in a refrigerator at 4° C overnight and then centrifuged for 1 h at 1,900*g*. The nucleoprotein was precipitated from the supernatant by addition of two volumes of absolute ethanol extended over a period of 3 h while agitating the contents of the flask.

The precipitated fibres of nucleoprotein were removed from the flask with a glass rod and washed three times with a solution of 75 per cent ethanol and then redissolved in 1,000 ml. of buffer containing 8·1 g sodium chloride and 5·25 g sodium citrate per l. (hereafter called 'standard buffer'). 90 ml. of a 5 per cent solution of sodium lauryl sulphate in 45 per cent ethanol was added to the solution of nucleoprotein. The mixture was stirred for 1 h and then enough sodium chloride was added to bring the final concentration of this salt up to 5 per cent.

This preparation was then placed in the refrigerator at 4° C and left overnight. The mixture containing the nucleoprotein was then centrifuged using a 'No. 40 Spinco' rotor at 19,000 r.p.m. The DNA in the supernatant was precipitated with ethanol as before. The precipitate was washed, redissolved and treated with the detergent as outlined. The last precipitate was dissolved in 120 ml. of the standard buffer solution and frozen. The residual protein in the DNA preparation was determined with the method of Lowry[9].

The DNA content of the final solution was estimated by the diphenylamine method of Dische[10]. The total nucleic acid content which would include the RNA component was determined according to the method of Spirin[11]. The molecular weight of the DNA was determined by the ultracentrifugal method of Burgi and Hershey[12].

Isolation of histones. Histones were obtained from the tumour nucleoprotein described. For this purpose the nucleoprotein was precipitated by addition to 6 volumes of water. The resulting fibres of nucleoprotein were lifted with a rod and placed into a flask containing N/4 hydrochloric acid. Next day the contents of the flask were centrifuged and the residue discarded. The supernatant was then treated with concentrated trichloroacetic acid (TCA) solution to precipitate the histones. Centrifugation of the TCA-treated solution yielded a yellowish sediment which turned white after washing with ether and acetone. The white powder was then dissolved in distilled water, dialysed against distilled water for 2 days, and finally lyophilized. The molecular weight of this histone preparation was determined by the ultracentrifugal method of Archibald[13].

Nucleoprotein isolation and characterization. Nucleoprotein from the tumour was isolated by the method of Mirsky and Pollister[14]. The fresh tumour was obtained from the dog, placed in dry ice, and afterwards stored in a deep freeze at −40° C. It was cut up in 1-cm squares for extraction. Repeated washing with saline citrate buffer, *p*H 7·2 (8·1 g sodium chloride and 5·25 g sodium citrate per l.), removed much of the cytoplasmic material. Residual saline-soluble material was removed by homogenization of the minced tissue in a Virtis '45' blender and centrifugation. This procedure was repeated three times. The residue was then homogenized in 1 M sodium chloride. Centrifugation of the resulting highly viscous solution gave a supernatant which was removed and stored overnight and a residue which was rehomogenized in a new portion of 1 M sodium chloride and also left to stand overnight. Next day the rehomogenized residue was centrifuged and the supernatants combined. The residue was discarded. When this nucleoprotein solution was poured into 6 volumes of distilled water, while swirling with a glass rod, fibres of nucleoprotein precipitated and wrapped around the rod. The rod was lifted, the nucleoprotein redissolved in 1 M sodium chloride, centrifuged and precipitated as before. This procedure was repeated four times. The final precipitate was dissolved in 1 M sodium chloride, rather than dried, and the DNA and protein content was determined using Dische's[10] and Lowry's[9] methods respectively.

The molecular weight of the canine haemangiopericytoma DNAP was $2{\cdot}35 \times 10^6$. The protein content of the DNAP was 66·6 per cent. The DNA content was 33·4 per cent. The molecular weight of the histones was 14×13^3.

Immunological testing procedures. The complement fixation and Ouchterlony procedure were carried out essentially as outlined in Kabat and Mayer[15]. The Arthus test was performed by injecting 0·05 mg of the various antigens in 0·1 ml. intracutaneously and reading the results after 10, 20, 30 min and at 24- and 48-h periods. Control tests were done on non-immune rabbits of the same age. A positive test was recorded when the control was negative and the area of redness, swelling and oedema was greater than 1 cm. The immunization schedule is outlined in Table 1. The antisera for the cross-reactions were obtained from rabbits challenged with the antigens listed in Table 3 (refs. 1 and 2).

The immunochemical data are tabulated in Table 2. The Arthus reaction was remarkably positive 17 days after the initial injection of the DNAP tumour. A qualitative precipitin test was positive 20 days after the initial injection of the experimental DNAP antigen. At this time there were no precipitin lines in the Ouchterlony test after 3 days of observation. The Arthus reaction was again positive 29 days after the beginning of the experiment. The Arthus tests were used not only to detect the presence of circulating antibody, but as a booster injection. The Ouchterlony test was repeated using normal control canine whole serum against the rabbit antisera, and the serum from the dog from which the tumour had been obtained. The Ouchterlony tests at this time were positive both with the normal dog serum and the serum from the experimental animal. The antisera were positive when tested against the DNAP fraction of the tumour with which the animal had been immunized initially. In view of the previous work[1,2] the rabbit antisera were tested against the canine serum protein fractions, namely, gamma-globulin, alpha-globulin, beta-globulin, albumin, fibrinogen and canine tumour DNAP and histone. The canine tumour DNAP fraction was negative. The Ouchterlony tests with the alpha-, beta- and gamma-globulin fractions showed precipitin lines with the beta- and gamma-globulins. The positive precipitin lines obtained with fibrinogen were against gamma- and beta-globulins. There was no precipitin line with albumin.

Immunoelectrophoresis was carried out in order to obtain a more precise definition of the precipitin lines involved. Three precipitin lines in Figs. 2 and

3 were obtained with immunoelectrophoresis. Two of these lines were identified as beta and gamma globulins. The third lines in Figs. 2 and 3 were not identified. No precipitin lines were obtained with the canine haemangiopericytoma histones and DNAP. The complement-fixation test was positive with dog tumour DNAP (Table 4).

The complement-fixation test was positive when gamma globulin and beta globulin were used as antigens against

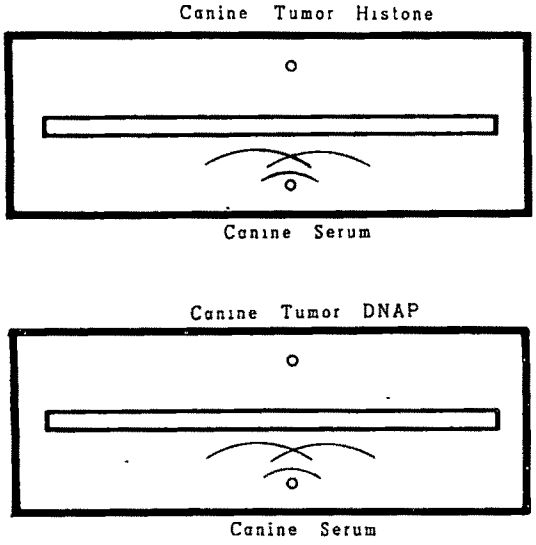

Fig. 2. Rabbit DNAP antisera were placed in the horizontal troughs. Canine haemangiopericytoma histones were placed in the upper well. There were no precipitin lines; there were three lines with non-cancerous canine serum. Canine haemangiopericytoma DNAP was placed in the upper well of the lower slide. There were no lines, whereas with non-cancerous serum there were three lines

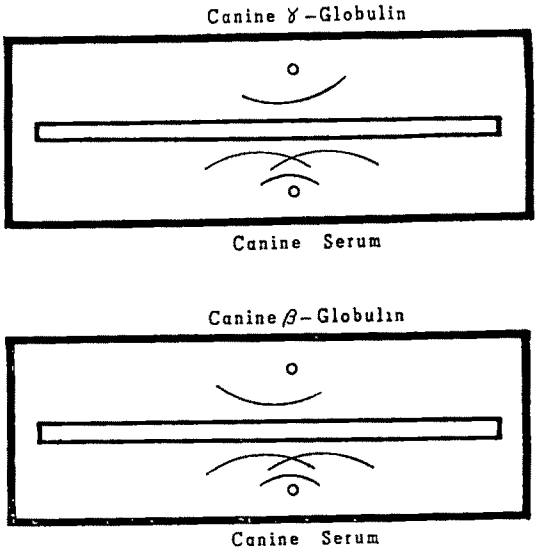

Fig. 3. Rabbit DNAP antisera were placed in the horizontal troughs. Canine beta- and gamma-globulin were placed in the upper well; one precipitin line was obtained with each. Serum from a non-cancerous dog was placed in the lower wells; three precipitin lines were obtained which correspond to the beta- and gamma-globulin lines. The third line was unidentified

the rabbit DNAP antisera. The rabbit antiserum was tested against the Hyland Laboratories' DNAP latex reagent and was negative in all sera except one. This was tested again and found to be negative.

Histological examination of the rabbit blood did not reveal lupus erythematosus cells. The serological cross-reaction tests with canine tumour DNAP and rabbit antisera against bovine DNAP, DNA, histones and salmine were negative as shown in Table 3.

The present work clearly indicates that there are trace amounts of antigenic constituents in DNA-protein (histone) complexes prepared by the method of Mirsky and Pollister. These antigenic materials may be present in association with the DNA in intact cells, while another possibility is that they are introduced into the DNA-protein complex only after breakdown of the nucleus during isolation. We have identified two constituents of our canine haemangiopericytoma DNAP preparation as beta globulins and gamma globulins using canine serum and serum fractions in immunoelectrophoretic studies with the rabbit DNAP antisera. A third immunoelectrophoretic precipitin line, the component of which is apparently isoelectric at *p*H 8·6, could not readily be identified.

One important observation in this experiment is that the antigenic components of the present dog tumour DNAP account for a very small percentage of the protein portion. The dog tumour DNAP itself did not give rise to Ouchterlony or immunoelectrophoresis precipitin lines in any case; dog tumour histone likewise failed to give positive serological reactions. This fact can be interpreted as follows: there are sufficient quantities of antigens in this dog tumour DNAP to elicit an antibody response in rabbits, while at the same time the antigen quantities are so minute that the sensitivities of known conventional immunological methods fail to give positive reactions. The results obtained in this investigation are consistent with the data previously reported concerning calf thymus DNA, DNAP and histones[1,2].

This work was supported in part by grants from the National Institutes of Health (*HE*–02153–09) and from the American Cancer Society (8709).

ALGAL INFLUENCE ON RADIONUCLIDES IN SETTLING PONDS

By JOHN ECHO and D. B. HAWKINS

Health and Safety Division, Idaho Operations Office, United States Atomic Energy Commission, Idaho Falls, Idaho

MANY of the larger processing plants handling radioactive material have an adjacent small pond through which low-level aqueous waste solutions are allowed to seep slowly into the ground. Such ponds exist for this purpose on the National Reactor Testing Station. They are a few acres in area and about 10 ft. deep, in gravelly alluvium, and transmit 10–100 gal. aqueous waste per ft.^{2} of basin per day. The chemical character of these solutions varies widely, the *p*H varies from 3–10, and the radiation field at the water surface varies from background to about 0·5 mr./h. Radionuclides contained in solutions moving through the basin sub-soil usually exchange on to the soil particles within a few tens of feet.

Particularly during the warmer months, dense algal blooms turn the pond waters into an organic broth. Although the β–γ radiation-level at the water surface may be only a fraction of 1 mr./h, dried debris (algae, detritus, etc.) which collects on the pond bank can give rise to general radiation-levels of 25 mr./h at 1 cm. The pond algae can itself produce fields up to 100 mr./h/g. Since it is well known that algae concentrate some radionuclides into their structure[1–3] the possibility exists that this mass of organic material could modify the chemical state of the radionuclide in solution, perhaps by chelation, and thereby alter its ion-exchange behaviour with the basin alluvium. Whether this would enhance or detract exchange was not known.

The purpose of our experiments was two-fold: (*a*) to determine if such a modification could be detected, and if so what effect it would have; and (*b*) to determine and evaluate the radiological hazards associated with algal growth in settling ponds.

Examination of the algal bloom showed that it was composed mostly of single-celled, floating or suspended members of the Desmidacae such as *Scenedesmus*, *Closterium*, *Cosmerium*, *Chlamydomonas*, and the like, about 80 per cent by occular estimate. The remainder consisted of *Pamella* and *Protococcus*-like organisms with other divisions represented by *Polycystis* and *Navicula*. Filamentous algae grew along the banks and sometimes in small rafts but did not contribute substantially to the mass of plankton.

Cultures of pond algae were grown in the laboratory plant-growth room in 5-gal. carboys. They were fed a standard nutrient solution and were sparged for 1 min in every 4 h for mixing. Radioactivity in the culture tank was essentially nil. Samples for experimentation were concentrated by centrifuge. The algae were then washed in distilled water, reconcentrated, and placed in 1-l. beakers. Approximately 5 g of wet algae were added to 1 l. of distilled water. 500 p.p.m. calcium was added as calcium nitrate, along with the test radionuclide, strontium-85 or caesium-137, and 5 p.p.m. stable strontium or caesium carrier. The *p*H of the contents of each beaker was then adjusted and maintained at 3·5, 7·0, or 9·0 using sodium hydroxide or nitric acid. At the time of the test each beaker had either 45 μc. strontium-85 or 20 μc. caesium-137. This rather austere regime was used in order to augment the effect of algal modification. The algae remained in these solutions for 3 weeks. The radioactive algae were then removed by centrifugation, washed to remove any activity from the growth solution, dried slowly and weighed. Each beaker contained about 1 g dry algae.

Coincident with the test-growth phase, twenty-four 1-l. beakers of algae were prepared and grown in exactly the same manner as the radioactive group but without the radionuclide. The conditioned water thus produced was used as a comparable leach solution in the experiment to follow. The non-radioactive algae were removed from the cold solutions and discarded. The washed, dried, radioactive algae from the growth phase were then placed in the comparable cold leach solutions and allowed to decompose in the dark for 2 weeks. The radionuclide incorporated either into or on to the algal cells was liberated by dissolution and isotopic exchange to the supernatant leach solution. At this time a third solution was prepared exactly like the first including the radionuclide but excluding the algae. This was used as a blank solution having no algal modification of any type. There were then three sets of solutions, at three different *p*H levels, to be tested and compared. These were (*a*) the original growth solution representing a pond with algae with the radionuclide in the water but not in the algae (growth phase); (*b*) the leach solution representing a pond with algae but with the radionuclide derived solely from nuclides cycled through the algal plant (leach phase); and (*c*) the blank solution representing a pond with algae, with the radionuclides in their original chemical form (blank phase).

Exchange studies were undertaken on synthetic alluvium which was prepared in the following manner. Distribution of particle sizes was determined by sieve analysis of typical alluvial deposits near the pond location. Representative size fractions of this material were then weighed out and thoroughly mixed together. This soil had a cation exchange capacity of 7·93 m.equiv./100 g for strontium and 5·87 m.equiv./100 g for caesium. 1 g of this soil was placed in a screw top vial along with 20 ml. of the test solution and rotated end over end for 24 h. The solution was then centrifuged, a 15-ml. sample removed by pipette, transferred to a counting vial, and counted in a well-type γ counter. The γ activity of the test solution was also determined in this same instrument. The distribution coefficient (K_d) of the material being tested in its test solution was defined to be the ratio of the activity on 1 g soil to the activity remaining in 1 ml test solution at equilibrium.

Table 1. Distribution Coefficients (K_d) of the Radionuclides Strontium-85 and Caesium-137 on Soil

Radionuclide	*p*H	$\bar{x}$ K_d	2*s*	Comparison
Strontium-85				Sr (growth phase)/ Sr (blank phase)

	9·0	—	—	

Finally, two experiments were carried out to determine the ratios of calcium/strontium and calcium/caesium selected by the algae from this system. Cold, washed algae were added to the same basic solution, 500 p.p.m. calcium as calcium nitrate, and 5 p.p.m. stable strontium carrier in 1 l. of distilled water. To this was then added approximately 50 μc. calcium-45. In the case of caesium, 5 p.p.m. stable caesium carrier was used in place of strontium (Table 2). Tests were run in triplicate.

The results of these experiments are listed in Tables 1, 2 and 3. As can be seen from the tabulated data, the distribution coefficients (K_d) for a given radionuclide in the growth phase or leach phase compared with the blank phase, in exchange on to the soil, are very similar. This indicates strongly that there is no detectable modification of the extent of exchange by cycling the radionuclide through the algal cells. There was a considerable difference in the K_d values for the exchange of strontium and caesium on the soil, that for strontium-85 being 3 and that for caesium-137 being 75 (Table 1). The low K_d for strontium is due to competition from calcium for exchange sites on the soil. In this system, the exchange of caesium is not appreciably affected by the calcium concentration. The relatively high K_d's for caesium are due to the marked difference for this element shown by the 10 Å clay minerals such as illite, the predominant clay mineral in this soil.

Table 2. Uptake of Radionuclides by Algae

Radionuclide	*p*H	μc. added	μc. on algae	Uptake (per cent)	m.equiv. inert carrier added	m.equiv. inert carrier on algae	Sr/Ca liquid	Sr/Ca algae	Enrichment factor
Strontium-85	3·5	45	3·51	7·8	$11·4 \times 10^{-2}$	$8·90 \times 10^{-3}$			
	7·0	45	3·46	7 7	$11·4 \times 10^{-2}$	$8 78 \times 10^{-3}$			
	9 0	45	3 78	8 4	$11 4 \times 10^{-2}$	$9·58 \times 10^{-3}$			
Calcium-45	7·0	42	0·13	0 31	25·0	$3·91 \times 10^{-2}$	$4·57 \times 10^{-3}$	$2 33 \times 10^{-1}$	50·8
Caesium-137	3 5	20	1·0	5 1	$3 76 \times 10^{-2}$	$1 92 \times 10^{-3}$			
	7 0	20	0 98	4·9	$3 76 \times 10^{-2}$	$1 84 \times 10^{-3}$			
	9·0	20	0·99	5 0	$3·76 \times 10^{-2}$	$1·88 \times 10^{-3}$			
Calcium-45	7·0	47	0 20	0·43	25·0	$5·3 \times 10^{-2}$	$1 51 \times 10^{-3}$	$3 51 \times 10^{-2}$	23 2

The uptake of caesium, strontium, and calcium by the algal mixture is similar to that shown by a strongly cross-linked ion-exchange resin in a system where specific interactions are absent.

The strontium/calcium ratio on the algae was 51 times greater than the strontium/calcium ratio in solution (Table 2). The enhancement of strontium over calcium is in keeping with the fact that for ions of the same valence, the ion exchanger becomes enriched in the ion with the smaller hydrated radius, in this case strontium.

As a rule, ion-exchangers prefer divalent to monovalent ions, and thus calcium should be preferred to caesium. However, the caesium/calcium ratio on the algae was 23 times that in the original solution. The enrichment of caesium is due to the smaller hydrated radius of the caesium ion as compared with the calcium ion. The caesium enrichment factor was half that of strontium because of the difference in valence between these two ions. Thus, in the caesium–calcium system, the size-charge effects are opposed, whereas in the strontium–calcium system the size-charge effects are acting in the same direction.

Table 3

Radionuclide	*p*H	Per cent	μc.
Strontium-85	3·5	6·5	0·23
	7·0	44·6	1·58
	9·0	43 4	1·54
Caesium-137	3 5	20·5	0·20
	7·0	98·0	0·98
	9·0	68 0	0·68

The similarity of the behaviour of the algal system to an ion-exchange resin is further illustrated by the following calculation: the cation exchange capacity for the algal mixture is about $4{\cdot}8 \times 10^{-2}$ m.equiv./g algae based on the total uptake of strontium and calcium. Knowing that $1{\cdot}88 \times 10^{-3}$ m.equiv. caesium/g algae was sorbed in the caesium–calcium system, there should, by difference, be $4{\cdot}6 \times 10^{-2}$ m.equiv. calcium/g algae. The calculated caesium enrichment factor for this system should be 27. These calculated values agree quite well with the measured quantity of $5{\cdot}4 \times 10^{-2}$ m.equiv. calcium/g algae and the measured caesium enrichment factor of 23.

The results for the uptake of strontium and calcium as reported here are not in agreement with those reported by Kevern for the green unicellular alga *Oocystis eromosphaeria*[4]. Kevern found that this alga took up strontium and calcium in direct proportion to the concentration of these elements in solution. The difference in behaviour of the alga in Kevern's system and that for the algal mixture in our system emphasizes Kevern's warning that the behaviour of one algal system cannot necessarily be extrapolated to another.

Regarding the release of strontium and caesium in our system (Table 3), the release of a higher percentage of sorbed caesium than strontium is probably due to the greater mobility of the caesium ions. Thus, strontium ions with their solvated shell should diffuse less rapidly through the algal membrane than the relatively unsolvated caesium ions. Stated another way, the reaction rate for the isotopic exchange of strontium should be slower than that for caesium, thus less strontium should be released.

Although the exchange behaviour of the radionuclides on the soil is not affected by cycling through the algal cell, the algae do concentrate radioactivity from very low levels in the water to rather higher levels in the algal aggregation. One gram of wet algae from the pond tested produced β–γ levels of 100 mrad/h at 1 cm. It is not difficult to imagine a migrant duck eating several grams of this algae. While this might not be hazardous for a single feeding, chronic feeding of resident ducks on a muscle seeker such as caesium might present an actual hazard. Wave and wind action throw algae on to the pond banks where it dries. Dried algae, flaking off the rocks, can become windborne and transported a considerable distance from the pond.

Finally, it appears that the algae not only concentrate radionuclides in their structure, but the release of these nuclides may be retarded for considerable lengths of time, especially in water of low *p*H. This might form a zone of high activity of undesirable magnitude at the soil–water interface, particularly if the pond were drawn down or drained for any reason. None of these hazardous conditions would develop in settling ponds free from algae. For these reasons it is recommended that an algicide be used to prevent the growth of algae in radioactive-liquid disposal ponds. The algicide used should not affect detrimentally the exchange behaviour of the radionuclides on the soil. It is suggested that algicides such as copper sulphate or sodium hypochloride should be used[5,6].

NATURE OF IMPULSE ORIGIN AND CONDUCTION IN THE MAMMALIAN HEART

RECENTLY, Dr. C. J. G. Wensing[1] has asserted his firm belief that both the origin and conduction of the wave of excitation in the mammalian heart are neurogenic. His article presents no evidence derived from experiments on the living heart and relies entirely on deductions from anatomical investigations. The article contains many misrepresentations of known facts about the nature of excitation and conduction in heart muscle and certain *ad hoc* assumptions which are required to make the mechanism proposed by his work.

Dr. Wensing states that the retardation of the impulse in the *A V* node is generally explained by pointing to the smaller dimensions of the *A V* nodal fibre. This is not true. Our own investigations[2], and those of others[3], have shown that conduction in fibres of the *A V* node is extremely slow and probably decremental in nature. Among the factors which might contribute to the slowness of this conduction is the small diameter of the fibres, but this is only one of many causes (such as different membrane properties, lower resting potential). Similar slowing and/or block of the impulse can occur in fibres of any diameter if there are appropriate changes in transmembrane potential[4].

Dr. Wensing states that it is impossible to show a direct connexion of specialized fibres between the *SA* node and the *A V* node and that "the explanation of the wave-like propagation of the impulse through ordinary muscle fibres is illogical and inadequate". This we believe to be false. Many recent investigations have indicated that there are tracts of muscle fibres which are both anatomically and physiologically specialized and which act as direct pathways from the *SA* node to the *A V* node[5]. But even if this were not so, there has never been any reason to doubt that conduction from one node to the other could occur through ordinary cardiac muscle fibres. Dr. Wensing states that the number of Purkinje

fibres in the myocardium is very small compared with the number of myocardial fibres so that a single Purkinje fibre would have to activate a considerable number of myocardial fibres. This is true. He adds that the occurrence of this is questionable in view of the non-syncytial nature of cardiac muscle. There is no reason to regard cardiac muscle as being non-syncytial. The recent observation that the intercalated disk has many of the anatomical properties of a membrane is paralleled by evidence that the intercalated disk has a low resistance to the flow of ions and current and does not represent a functional barrier to impulse transmission.

Dr. Wensing would seem to believe that fibres of the Purkinje system are the only fibres in the heart which are able to conduct excitation. (We can see no other explanation for the weight he places on his observation that Purkinje fibres are rare in the atrium, cannot be shown to connect the *SA* node and the *AV* node, and must excite many myocardial fibres in the ventricle.)

Dr. Wensing states that the histological structure of the *SA* node and the *AV* node provides no sound basis for explaining their function. In fact many investigators have found the *SA* node and the *AV* node to be histologically distinct from other parts of the heart. We are unable to imagine how one could predict from histological examination that a particular structure had the ability to generate impulses.

Dr. Wensing states that previous investigators have been misled in their identification of the location of the *SA* node by the presence of a nearby structure in the sulcus terminalis which possesses thin fibres and a considerable amount of connective tissue in the interfibrillar meshes. Dr. Wensing, however, identifies the *SA* node as being the area which stains most intensively with his acetylcholinesterase stain. In this conclusion he may or may not be correct, but in no event has he identified the *SA* node of the living heart by any of its functional properties and shown that the site so identified corresponds to the area located by his stains.

Dr. Wensing asserts that the generation of the impulse results from the action of the dense network of autonomic interstitial cells. He further asserts that these cells cause the muscle cells to contract by secreting a "neurosecretory product". We believe that this conjecture lacks any experimental support.

Dr. Wensing supposes that the delay which occurs at the *AV* node results from the fact that the nerve network becomes intensively plexiform and meshlike at the *AV* node. He offers no evidence that conduction in such a mesh would be slow. He also suggests that the network of autonomic interstitial cells between the meshes of this plexus generates the beats which occasionally arise at the *AV* node.

Dr. Wensing remarks that although acetylcholine does not penetrate ordinary nerve fibres it may well penetrate the nerve fibres of which he speaks and that such penetration explains why acetylcholine causes *AV* block. This would seem to be little more than conjectural.

We find, therefore, that the only demonstrative evidence in the article by Dr. Wensing consists of his anatomical descriptions of a network of nerve fibres intimately associated with the *SA* node, the *AV* node and the bundle of His. The rest we believe to be surmise.

Against this we may place the results of some 80 years of investigation which we have reviewed elsewhere[2] and which shows among other things that: (1) Cardiac muscle fibres conduct excitation as if they were syncytially interconnected. (2) The cells of the *SA* node, when investigated with intracellular microelectrodes, behave exactly as they would be expected to if they were the source of the action potential. They show spontaneous depolarization during diastole, and the slope of this spontaneous depolarization changes in the expected way under the influence of all physical and chemical agents which alter the heart rate. (3) Cells which show spontaneous depolarization during diastole are found in those parts of the heart which have long been known to be possible sites of origin of extrasystoles. (4) The spread of excitation from the *SA* node to the *AV* node has been mapped by the use of intracellular and extracellular recording. A full and complete parallelism exists between the spread of excitation and the spread of the action potentials in the appropriate cardiac cells. (5) Exactly analogous arguments apply to the spread of excitation in the *AV* node, the His-Purkinje system and the ventricular myocardium. In each case the spread of excitation corresponds exactly to the spread of the action potentials of the appropriate cells. (6) The electrical activity of single cells of the *AV* node, like that of single cells of the *SA* node, changes in exactly the way one would expect if transmission through those cells determined both the *AV* nodal delay and the variations in that delay which result from the action of physical and chemical agents.

In brief, we believe that Dr. Wensing has ignored an extensive, complex and extremely well-documented set of facts which have provided an almost complete picture of how the cardiac impulse arises, how it spreads and how it is influenced by physiological and pharmacological changes. In place of this, he offers a set of facts about the anatomy of certain nerves, a number of apparently incorrect assertions about the traditional view, a number of *ad hoc* assumptions about possible mechanisms, and no experimental information whatsoever.

It should be noted that the nerve network postulated by Dr. Wensing has the following properties: (1) it is heavily concentrated at the *SA* node and generates impulses in the same way as does the *SA* node; (2) it connects the *SA* node and the *AV* node in the same way as do the fibres of the atrium; (3) it is heavily concentrated at the *AV* node and is there subject to slow conduction just as *AV* nodal fibres are; (4) its peripheral distribution is exactly that of the His–Purkinje system.

Dr. Wensing thus replaces the traditional configuration of cardiac cells responsible for impulse generation and conduction in the heart by a nerve network of identical configuration and functional properties. He further requires that a conjectural system of autonomic interstitial cells transmit excitation from this nerve network to cardiac cells immediately adjacent to it throughout its entire course.

There would seem to be no reason for regarding impulse origin or conduction in the mammalian heart as neurogenic.

Brian F. Hoffman

Electrophysiological investigations of the specific conductive tissue in the heart are based on the derivation of action potentials. These are physical phenomena which can be initiated by chemical changes. If one rejects this assumption, a further discussion has no sense. The chemical processes which cause these changes in potential may themselves be initiated by intrinsic (that is, inherent to the fibres) or by extrinsic (that is, beyond the territory of the proper fibre) factors.

The crucial question is, what must be considered the initiator of the heart beat? Is it the chemical processes,

which secondarily cause changes in potential, or is it the changes in potential themselves? Prof. Hoffman and Dr. Cranefield's arguments will be discussed in sequence.

They state that the small diameter of the nodal fibres is not a valid argument for the *A V* delay in itself, although they admit that the specific diameter may play a part in the entire process. In Paes de Carvalho's paper[1], as well as in my own[2], the greater diameter of the nodal fibres was emphasized. When the data of Paes de Carvalho and Truex[3] are compared, it appears that scarcely any difference exists between the diameter of the nodal fibres in the stratum which reveals the greatest delay, on one hand, and the atrial fibres, on the other. I fully agree with Prof. Hoffman and Dr. Cranefield that there are more causes for this great delay, among others, the various membrane-characteristics. From papers cited by them[2,4] it would seem that these characteristics vary, depending on the nature and period of the excitation and, moreover, on pharmacological influences. The concentration of acetylcholinesterase is highest exactly in the middle part of the node. The question should then arise of whether these membrane-characteristics are specifically inherent to the cells under consideration, or initiated by specific reactions of these cells which are induced by their environment.

Prof. Hoffman and Dr. Cranefield start axiomatically from the assumption that conduction is solely inherent to specific fibres. In this respect, one of Prof. Hoffman's experiments[5] deserves closer attention. He states that in preparations of Purkinje fibres, the transmission of impulses may be delayed or even blocked if adequate changes occur in the transmembranous potential. Moreover, in his paper he points out that during an intracellular excitation of a Purkinje fibre, the response at the second electrode in the fibre, situated at a greater distance from the source of the impulse, is registered in advance of one closer to this source. When examining the experiment more closely, it is assumed that it is possible to derive potentials from isolated Purkinje fibres with mutual distances of more than 1 mm. The registration of intracellular potentials, with which I am familiar, is a considerable achievement; but the registration of potentials from a single fibre at so great an interval is even greater than that.

The foregoing implies that the action potentials registered by Prof. Hoffman and Dr. Cranefield will be initiated by various Purkinje fibres. Moreover, when applying intracellular stimulation, there must be a subsequent conduction perpendicular or oblique to the longitudinal axis of the fibre. In this case, more structures must be penetrated than a single intercalated disk alone; that is, two cell membranes and the intercalated connective tissue. It seems improbable that this conduction occurs through anastomoses between the fibres, the more so since anastomoses are seldom encountered between Purkinje fibres which show a straight course. Notwithstanding this fact, there would seem to be the possibility of conduction and the only factual substrate appears to be the intercalated nervous network.

There is a considerable number of papers on the occurrence of specialized muscular tissue in the atria, but the number of those describing direct anatomical connexions between both nodes is very limited[6,7]. A closer examination of these papers shows that they are vulnerable to considerable criticism. I have already listed the physiological data supporting direct conduction.

According to recently published data[8], the separation between cardiac muscle cells has no physiological bearing, which suggests that I probably attached too much importance to the function of the intercalated disk. The question arises, however, of whether the existence of an electrical synapse between various bundles of muscular tissue is feasible.

Prof. Hoffman and Dr. Cranefield agree with me that the histological structure of both nodes does not constitute a sound basis for explaining their function, as it would be difficult to derive a function from a structural basis. When describing the nervous network in the *SA* node, however, I made a comparison with the marginal organ of the jellyfish. This organ shows not only a close morphological resemblance to the *SA* node, but also a functional one.

On studying the relevant literature, one arrives at the conclusion that a small number of investigators has been misled in their identification of the *SA* node[9]. I do not hesitate, therefore, to identify the described nervous network with the *SA* node, the more so since it is a simple matter to distinguish between the nervous network and the nodal cells in Champy–Coujard preparations. Moreover, the exact location of the *SA* node in two pig hearts has been determined by direct electrophysiological registration with the aid of the Durrer-team.

I should like to emphasize that the nerve stainings which were applied to trace the nervous network have been based on the visualization of compounds occurring in that network; that is, catecholamines and acetylcholinesterases.

There are no experimental data on the conduction in those structures which I described in the *A V* node, but it is well known that the velocity of conduction depends to some extent on the diameter of the fibre. In the central part of the plexus the diameter is smaller, whereas the distance to be covered in a plexus is considerably longer.

The assumption that the *A V* rhythm is initiated by the nervous network in the meshes between the plexus was, in fact, based on the same considerations as were given when the *SA* node was dealt with. It would be inconsequent to interpret functionally the structure of the *SA* node and to ignore that in the *A V* node.

Prof. Hoffman and Dr. Cranefield are partly correct in blaming me for not taking sufficiently into account the existing ideas on excitation and conduction of impulses. On the other hand, however, I did not, and do not, ignore these concepts. It is beyond any doubt that specialized muscular tissue has a definite function in the conductive process, but I repeat that it is my firm belief that the nervous component is of primary importance. The precise interaction of both structures, however, is not yet known. In this respect it is appropriate to refer to the great histological differences which occur between the conductive tissue in ungulates and carnivores.

I agree with Prof. Hoffman and Dr. Cranefield that it is difficult to derive functional data from a histological basis. It was for this reason, therefore, that my paper was entitled: "Evidence for . . . etc.". I emphasized the fact, however, that it is also intolerable to ignore histological data when interpreting electrophysiological results. I cannot accept Prof. Hoffman and Dr. Cranefield's views that the nervous structures referred to here have no excitative or conductive function.

HYDRODYNAMIC ANALYSIS OF DOLPHIN FIN PROFILES

By THOMAS G. LANG
U.S. Naval Ordnance Test Station, Pasadena, California

DOLPHIN fins have well-streamlined cross-sections that may be useful as hydrofoils or airfoils designed to operate in the Reynolds number range around 10^6. Possible applications might be torpedo fins and propeller or pumpjet blades, boat propellers, rudders, keels, struts and hydrofoils, helicopter rotor blades, windmill vanes, and sailplane wings and control surfaces.

Photographs of cross-sections of one dolphin tail fluke and two dorsal fins were obtained from animals that had died of natural causes. The cross-sections were obtained about midway between the bases and the tips of the three fins. Fin offsets were measured from the photographs and plotted on a 2-m scale. The best curves possible were drawn through the measured points; the maximum deviation being 0·2 per cent or about 0·02 cm. About eighty points were read from the 'best' curves and run on an IBM 7094 computer at the Naval Ordance Test Station to obtain pressure distribution using the Douglas two-dimensional airfoil programme which assumes potential flow. Pressure distribution is generally the most significant factor in analysing the performance of hydrofoil or airfoil cross-sections.

The profiles and pressure distributions of the three fins are shown in Fig. 1. Fin *A* is a tail fluke section of a common dolphin (*Delphinus bairdi*), fin *B* is a dorsal section of a Pacific striped dolphin (*Lagenorhyncus obliquidens*), and fin *C* is a dorsal section of a Dall porpoise (*Phocoenoides dalli*). The lower portion of Fig. 1 illustrates the upper half of the cross-section of each fin; the semi-thickness to chord ratio, y/c, is plotted against chord length from the leading edge. The upper portion of Fig. 1 shows the pressure distribution where:

$$C_P = \frac{P - P_0}{\rho\, V_0^2/2}$$

and P_0 is the depth pressure, P the local static pressure on the fin, ρ, mass density of the flowing fluid, and V_0, the fluid speed relative to the fin.

The fin chord lengths are between 12 and 18 cm long. The fin offsets are listed in Table 1. The effect of angle of attack on the pressure distribution of fin *A* is shown in Fig. 2. Maximum thickness and its location, leading edge radius, trailing edge thickness, and minimum pressure coefficient, C_p, and its location are listed in Table 2.

The three fins are similar in that their maximum thicknesses are all located between 32 per cent and 36 per cent chord length of the leading edge; all are fairly thick (15·2 per cent to 21·1 per cent chord length) and have a relatively large leading edge radius (2·4 per cent to 4·2 per cent chord

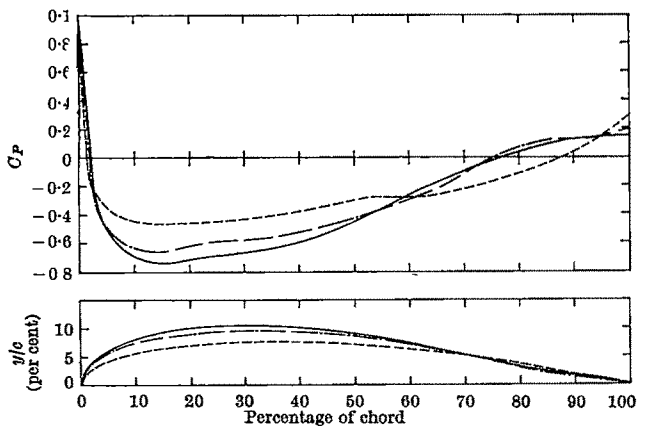

Fig. 1. Profiles and pressure distributions of three dolphin fins. *A*, ———, Tail fluke of common dolphin, *B*, – · – · –, dorsal fin of Pacific striped dolphin, *C*, - - - - - -, dorsal fin of Dall porpoise

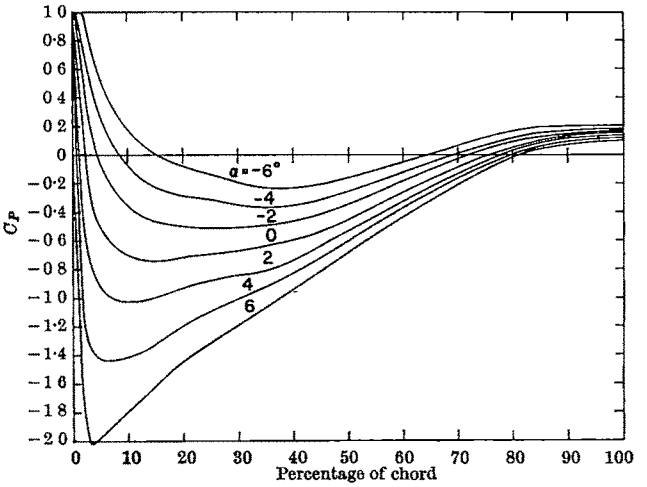

Fig. 2. Effect of angle of attack on the pressure distribution of Fin *A*

length); their minimum pressures are located between 14 per cent and 16 per cent chord length of the leading edge; all have a fairly long region of gentle adverse pressure gradient (increasing C_p) followed by a steep adverse pressure gradient; all trailing edges are relatively thin, and tail fluke *A* and dorsal fin *B* have cusped trailing edges. Fins *A* and *B* are surprisingly similar since they are cross-sections of different kinds of fins from different species. Fin *C* is a thinner section and came from Dall porpoise, reported to be the fastest of the three species[1].

All fins were generally symmetrical although some warpage appears in the photographs near their trailing edges. Fin offsets for the computer study are based on the semi-thickness and, therefore, symmetrical sections. The pressure distribution is strongly affected by small changes in fin profile; consequently, some of the minor waviness in the pressure distributions of Figs. 1 and 2 may not be real.

Analysis of the fin pressure-distributions indicates that the fin sections are ideally designed for operation at Reynolds numbers, R_e, in the vicinity of 10^6 where these fins operate. The low-drag airfoil sections designed for airplane wings operating at R_e around 10^7 and above are relatively poor in the range of $R_e = 10^6$, since the laminar boundary layer extends too far into the adverse pressure gradient region and separates, causing excessive drag[2].

Table 1. Dolphin Fin Offsets

Distance from nose (% chord)	Fin semi-thickness (% chord)		
	Fin *A*	Fin *B*	Fin *C*
0	0·00	0 00	0·00
2	3·97	3·80	2·84
5	6·07	5 71	4·24
10	8 05	7·44	5·61
15	9·28	8·51	6·48
20	9·96	9·12	7·04
30	10·53	9·65	7 62
40	10·17	9 46	7·56
50	8·98	8·60	7·42
60	7·20	7·19	6 43
70	5 22	5·28	5·35
80	3·16	3·22	3·85
90	1·57	1·74	2 08
100	0 23	0 45	0·14

Table 2. Dolphin Fin Characteristics

Fin designation	Maximum thickness (% chord)	Distance from nose to max. thickness (% chord)	Leading edge radius (% chord)	Trailing edge thickness (% chord)	Minimum C_P	Distance from nose to min. C_P (% chord)
A	21·1	32	4·2	0·46	−0·74	15
B	19·3	33	3·8	0 90	−0·66	14
C	15·2	36	2·4	0 28	−0·46	16

The fin pressure-distributions are not similar to the more commonly known airfoils[2,3]. The fin profiles are a compromise between the less-known special airfoils *FX*05-191 by Wortmann[4] and *EA*6(-1-)-018 by Eppler[5] designed for the R_e region of 0·5–3·0 × 10^6. The differences between the designs of Wortmann and Eppler are sufficiently great to indicate that a compromise design is significant and may have unexpected beneficial characteristics. The favourable pressure gradient near the nose and the gentle adverse pressure gradient to trigger turbulence, combined with the cusp-shaped pressure gradient of fins *A* and *B* to provide a near-uniform boundary layer form parameter, appear to optimize the length of laminar flow and eliminate both laminar and turbulent boundary layer separation. The difference in adverse pressure gradient shape of fin *C* from those of fins *A* and *B* may be due to its reduced thickness ratio. Thinner sections of a given airfoil family have reduced adverse pressure gradient; consequently, the adverse pressure region can be shifted backwards and modified without causing turbulent boundary layer separation.

The thicknesses of the trailing edge of the fins lie between 0·28 per cent and 0·90 per cent chord length. Airfoils experience essentially no drag increase for thickness ratios up to about 0·5 per cent chord length at R_e around 10^6 and only a small drag increase at 0·8–1·0 per cent thickness ratios[6]. The photograph of fin *B* showed evidence of slight deterioration, so its trailing edge may not be as thick as reported.

The thick-fin sections are probably needed primarily for strength. Thick sections also permit greater angle-of-attack, α, variations without producing excessive minimum pressure peaks at the leading edge that can result in flow separation and cavitation. Fig. 2 indicates that two-dimensional fin angles of attack up to 4° (7° for a fin aspect ratio of 4·0) should be permissible without producing separation and high drag. This angle is in the reasonable range of maximum α for propulsion by fluke undulation and for dorsal fin angle of attack resulting from manoeuvring. During acceleration at low speed, the fluke angle of attack could be considerably greater since added drag is not so important and the fluke would not stall until α reached about 20°.

From the point of view of cavitation, fins *A*, *B*, and *C* at $\alpha = 0°$ should reach speeds of 16·3 m/sec (31·6 knots), 17·3 m/sec (33·6 knots), and 20·7 m/sec (40·2 knots), respectively, before cavitating near the water surface. However, a realistic angle of attack is about 3° or 4°. Fin *A* would cavitate at 13·9 m/sec (27·0 knots) at $\alpha = 2°$, 11·7 m/sec (22·7 knots) at $\alpha = 4°$, and 9·9 m/sec (19·2 knots) at $\alpha = 6°$. It is likely that cavitation would be avoided by dolphins since cavitation is known to produce considerable surface damage to metals and might be painful to dolphins. If the fin profiles had been thinner or if the maximum thickness had been more rearward, the nose radius would have been smaller, making cavitation begin at much lower speeds at $\alpha = 4°$ but at higher speeds at $\alpha = 0°$.

Maximum speeds of tame dolphins trained for speed runs are 7·7 m/sec (15 knots) for the Pacific striped dolphin[7], 8·3 m/sec (16·1 knots) for the Pacific bottlenose dolphin[8], and 11·0 m/sec (21·4 knots) for the Pacific spotted dolphin[9]. Maximum top speed reported in the technical literature for the common dolphin is 10·3 m/sec (20 knots)[10].

I thank Dr. Samuel Ridgeway for sectioning the dolphin fins and supplying photographs and Mr. Dave Nelson for advice and for helping to operate the computer programme.

LOCALIZED HYPERCHONDROPLASIA INDUCED BY CRUDE PAPAIN ADMINISTERED TO MICE

By Prof. HOWARD K. SUZUKI
Department of Anatomy, University of Arkansas School of Medicine, Little Rock, Arkansas

MICE can tolerate a single injection of up to 50 mg/kg body-weight of crude papain when injected intravenously; this is significantly higher than the amount of papain that can be tolerated by rabbits or guinea-pigs[1]. Two injections of papain given to mice on consecutive days usually result in the closure of the proximal tibial epiphyseal plates[1].

This article presents results of investigations of the effects of papain on the epiphyseal plate in tibiae when relatively low doses of papain are administered to mice.

Crude papain was prepared fresh in 0·9 per cent saline, and the solution was filtered before use. Female Charles River white mice weighing approximately 25 g were divided into three groups: group I, ten control mice were injected subcutaneously with 0·10 c.c. 0·9 per cent saline for 5 consecutive days; group II, ten mice were injected with 1·0 mg of papain in 0·10 c.c. 0·9 per cent saline for 5 consecutive days; group III, sixteen mice were injected with 1·0 mg of papain in 0·10 c.c. 0·9 per cent saline on the first and third day of the experiment. All the mice were killed on day 21. The tissues were prepared for histological investigation using Peterfi's double-embedding method and stained with Mallory's stain or periodic acid–Schiff (PAS) as previously described[2].

In the control group, the epiphyseal plates of the tibiae and femora comprised orderly arranged columnar rows of chondrocytes. The proliferating cells were transversely compressed with deeply staining nuclei and cytoplasm and ranged from 8 to 14μ in length. The mature and senescent chondrocytes had vesicular nuclei and vacuolated cytoplasm with some PAS-positive granules. They were hypertrophied and attained sizes ranging from 11–20μ. The metaphysis was comprised of longitudinally arranged trabeculae of bone with calcified cartilage cores (Figs. 1–3).

The group given 1 mg of papain daily for 5 consecutive days was the only one of the three groups which suffered from the toxic effects of papain. In this group, four out of ten mice died before the termination of the experiment. The most striking feature of this group was the almost complete destruction of the epiphyseal plates of both femora and tibiae in all the remaining mice. The few remaining chondrocytes were irregularly arranged (Figs. 4–6). These features are in accord with earlier published descriptions[1]. The metaphysis was comprised of few

trabeculae which, when present, were somewhat heavier than the control group.

In the mice given 1 mg of papain per injection on two alternate days, the femoral epiphyseal plates were bilaterally destroyed in all the mice in this group (Fig. 7), and had a similar appearance to those of the 5 mg papain-treated group. However, in the tibiae, only six out of sixteen mice presented this bilateral pathology. In the remaining ten mice, the tibiae had greatly widened epiphyseal plates due to hyperchondroplasia of the proliferating chondrocytes (Figs. 8–9). This manifestation was observed in both right and left tibiae in four of the mice, and only in the left tibiae in the remaining six. The proliferating chondrocytes were not only significantly increased in number but also in size (8·5–29μ), and became irregularly arranged. The cells were deeply staining, with PAS-positive granules in the cytoplasm, and were not compressed as in the normal mice but were variously shaped (Fig. 9). Only a few mature and senescent hypertrophic cells were present, and they were located in areas adjacent to the active invasion of metaphyseal capillaries. These cells had vesicular nuclei and vacuolated cytoplasm containing PAS-positive granules; they were larger than the same cell types in the controls, ranging from 20 to 29μ in size. The metaphysis was comprised of a

transverse stratum of bone which formed adjacent to the undersurface of the cartilaginous plate. The longitudinal trabeculae had all but disappeared, indicating an almost complete inhibition of osteoblastic activity. This was similar in appearance to the growth arrest phenomenon which was due to nutritional deficiencies[3].

In some of the mice tibiae, papain no longer appeared to interfere with the metabolism of the chondrocytes. This was manifested by the reappearance of maturing and senescent epiphyseal chondrocytes with concomitant invasion of capillaries to break down the chondrocytes (Figs. 10 and 11), and is similar to the recovering phase of Park's nutritional deficiency experiments[3]. Thus, the epiphyseal plate began to have a normal appearance again.

Low doses of papain administered to mice appear specifically to alter the normal metabolism of specific chondrocytes, yet to allow them to proliferate. The process of orderly maturation and senescence is interfered with, but the mechanism by which this occurs is not known. I can only concur with Park's conclusion[3] that the "capillary-osteoblast complexes had been powerless to invade the cartilage until the maturation of the cartilage cells had been completed"[3].

This investigation was supported by a U.S. Public Health Service grant *AM*–02745–07, from the National Institutes of Arthritis and Metabolic Diseases.

SOMATICALLY UNSTABLE MUTANTS OF *Aspergillus nidulans*

By ALAN UPSHALL
Department of Genetics, University of Birmingham

SOMATICALLY unstable mutants have, for obvious reasons, been largely ignored in mutation studies and excluded from breeding experiments. Nevertheless, it is becoming clear that they may constitute an important and frequent class of hereditary changes[1–9], and their occurrence and properties must be accounted for in any comprehensive theory of mutation. In the *Aspergilli* such mutations are relatively common and in a few cases their origin has been traced to extrachromosomal[10–13] and chromosomal[14] causes. To pursue the problem further, unstable mutations have been specifically sought in *Aspergillus nidulans* both spontaneously and following treatment with mutagens. The present article describes the frequencies and some of the properties of unstable morphological mutants that occur spontaneously in this species.

To determine the frequency with which unstable mutants arise, conidia, hülle cells and ascospores of Birmingham wild-type isolates, 1, 26, 27 and 36, and their white and yellow spore colour derivatives (obtained by ultra-violet irradiation) have been examined. These isolates belong to heterokaryon compatibility group *B* (ref. 15), and as such are thought to have basically similar genetic backgrounds[16]. Since their isolation, from the Birmingham area, all have been kept in stock tubes at 5° C, being propagated by mass hyphal transfers every 3 months.

All colonies were grown on a modified Czapek minimal medium (containing KH_2PO_4 instead of K_2HPO_4), solidified by New Zealand Agar (supplied by G. T. Gurr, Ltd., London), the plates being incubated at 25° C. Conidial suspensions were obtained from 10-day-old colonies (propagated from the stock tubes by mass

	Totals	210,702	0·180								357	23

hyphal transfers). Mature perithecia were sampled individually, twenty being selected at random. Attached conidial heads were removed and the hülle cells, obtained by rolling the perithecium over the surface of an agar plate, were spread. The clean perithecia were then burst individually and four samples of ascospores were taken from each. All plates were examined for abnormal colonies after 7 days' incubation and such colonies were tested by growing samples of their conidia and by making mass hyphal transfers. Mutants were classified as unstable if, on propagation by conidia, the colonies produced were of two types, mutant and normal, and if normal sectors were produced by the mutant colonies.

The frequencies and types of mutants obtained are summarized in Table 1, and the main features are as follows: (1) The mean frequency of mutant colonies over all strains is $1{\cdot}8 \times 10^{-3}$. (2) The relative frequency of unstable to stable mutants is 16 : 1. (3) Ascospores consistently give the greatest frequency of unstable mutants. (4) There are only four general classes of unstable mutants, namely, *Crimson*, *Mycelial* (not to be confused with the *Mycelial* described by Roper[17]), *Fawn* and *Minutes*. The minute class can, however, be subdivided into 3 phenotypically distinct classes each having in common a much slower growth rate than the normal. (5) There is no evidence that the frequency of unstable mutants differs between the various spore colour strains of the same wild isolate. The data, given in Table 1, have therefore been pooled over the spore colour variants.

The mutants have the following descriptions:

Crimson, white when young, turning through orange to a bright crimson at about 7 days. Conidia are few and smaller than normal. Growth rate is approximately 0·8 of normal.

Mycelial: white mycelium with golden patches of hülle cells especially in the centre. Conidia few and very small. Growth rate is approximately 0·9 of normal.

(The foregoing two mutants were first described by Croft[13].)

Fawn: fawn colonies with fewer, slightly smaller conidial heads than on a normal colony and also very small abnormal heads. Growth rate is approximately 0·8 of normal.

Minute, type a: this is phenotypically identical to the minute variant described by Faulkner and Arlett[18]. Growth rate is approximately 0·4 of normal. *Type b*: pinkish with a knobbly appearance due to stunted hyphal growth and a cover of hülle cells. Conidia few and very small. Growth rate is approximately 0·3 of normal. *Type c*: this is density dependent, greyish if small but covered with hülle cells and pale yellow if large, but at all densities they have characteristic abnormal heads. Growth rate is approximately 0·4 of normal.

The 'other' category of Table 1 consists of unstable mutants which only occur very rarely.

A comparable investigation has been carried out on Birmingham isolate 29 and strain 29*y*. These belong to heterokaryon compatibility group *A* (ref. 15) and are therefore thought to have a basically different genetical background from group *B* (ref. 16).

The results show that unstable mutants are also present in this group with an equally high frequency (Table 2). They are, however, phenotypically different from those obtained from heterokaryon compatibility group *B*. Here the relative frequency of unstable to stable mutants is 24 : 1, with ascospores again giving the greatest frequency. There is, however, a significant difference (P for $\chi^2 < 0{\cdot}001$) for the total number of mutants between the two spore colours.

The high frequency of unstable mutants recovered in the samples of spores and cells from the colonies of the thirteen strains examined could arise from two alternative effects: (i) a high mutation rate to the unstable state; (ii) a low mutation rate coupled with the accumulation of unstable mutants within the colonies propagated by mass hyphal transfers because they are either not selected against, or are actually favoured by selection during the growth of a colony.

To distinguish between these alternatives two types of colony from the same strain were examined for the frequency and types of unstable mutants they gave rise to when propagated by conidia. These were (*a*) colonies that had been maintained entirely by mass hyphal transfer from the time the isolates were first obtained from the wild, and (*b*) colonies with normal phenotypes that had been initiated from single conidia 7 and 10 days before the frequency of unstable mutants was determined. It is possible that in the first type of colony (*a*), unstable mutants accumulated over a period of many years. In the second type of colony (*b*), however, unstable mutants could only have arisen since the colony was initiated by a wild-type haploid spore, either 7 or 10 days previously. Irrespective of the method of propagation and their age, all the colonies yielded the same range of types of unstable mutants (Table 3). A χ^2 analysis of the total frequency of unstable mutants showed no significant difference between them ($\chi^2_2 = 0{\cdot}053$). Thus there is no evidence that these mutants are accumulating in the mass hyphal cloned material.

Two further sets of observations support this conclusion. First, because all the unstable mutants have slower rates

Types and frequencies of mutants obtained from colonies of the same isolate propagated in different ways: *a*, by mass hyphal transfers of an old clone, b_1, by single conidia 7 days before sampling; b_2, by single conidia 10 days before sampling.

of growth than the normal strains from which they arise (see earlier) they are continually being overgrown by the normal sectors to which they invariably give rise. Secondly, the mutants, once they arise, are almost impossible to retain by any normal method of propagation. Indeed, it is only possible to retain the mutant phenotype for more than a single propagation by continual propagation with conidia from the mutant areas of the mutant colonies.

In view of these findings it seems extremely unlikely that there has been any accumulation of unstable mutants in the long-standing isolates. On the contrary, it seems more likely that the estimate of the frequency of unstable mutants is minimal in that many mutant spores and cells may revert to normal before they produce a scorable macroscopic colony. Thus it can be assumed that the high frequency of unstable mutations is due to a high mutation rate.

These investigations have shown that the spontaneous rate of mutation to an unstable state is very high. Thus the highest rates observed in these experiments, which are probably minimal estimates, are $5{\cdot}8 \times 10^{-4}$ for *Crimson*, $6{\cdot}9 \times 10^{-4}$ for *Mycelial* and $7{\cdot}3 \times 10^{-4}$ for minute *type a*, all from ascospore samples (Table 1). Apart from the exceptionally high spontaneous mutation rate to the vegetative petite condition in certain strains of yeasts, these spontaneous mutation rates for the unstable mutants are among the highest recorded (see table in ref. 19).

A further similarity with vegetative petite is that these same types of unstable mutants can be specifically induced with mutation rates as high as 100 per cent with various acridine dyes[13,20]. Whether or not these mutants are also like vegetative petites in being extrachromosomal mutations is at present being investigated. The evidence so far is equivocal, neither fitting a conventional extrachromosomal explanation nor a conventional chromosomal one. Whatever the outcome of any further analyses, it is already clear that the unstable mutants possess many novel properties in addition to their high mutation rate.

I thank Prof. J. L. Jinks for guidance and criticism during the preparation of this report, and the Science Research Council for a research studentship.

CHANGES IN MITOTIC ACTIVITY DURING EARLY CALLUS DEVELOPMENT

By Dr. M. M. YEOMAN, P. K. EVANS and G. G. NAIK
Department of Botany, University of Edinburgh

WHEN an inoculum is taken from a tuber of Jerusalem artichoke, *Helianthus tuberosus*, and transferred to a suitable medium a callus culture is established, the development of which depends on vigorous cell division. For the analysis of at least the early stages of the process, the state of the cells with respect to the division cycle at the time of excision is a matter of some significance and it is this which is the subject of this article.

The observations that are presented have been made with cultures grown on an agar medium which contains a mineral salts mixture, sucrose, 2 : 4-dichlorophenoxy acetic acid and coconut milk. Essentially similar results have also been obtained using a liquid medium of the same composition[1]. After a lag phase (the length of which depends on the age and state of the tuber from which the inoculum is taken) rapid division begins. These early divisions are in the superficial layers only[2]. The first divisions occur in the outermost layers of cells and with these the long axes of the spindles are predominantly parallel to the surface. With subsequent divisions the spindle is at right angles to the surface, giving rows of cells also at right angles to the surface.

Important evidence regarding the initial state of cells is provided by observations on the course of change in the number of cells with time. The results of one set of such determinations are presented in Fig. 1. These results were obtained with an experimental design which has been described in detail elsewhere[2]. It is evident that even after division begins increase in the number of cells does not occur uniformly with time. In the cultures of this experiment there is no change during the first 36 h, but afterwards an abrupt increase occurs which is completed within a few hours. This is followed by a period of about 12 h during which the number of cells remains constant. After this a second abrupt rise is observed. It may be emphasized that it is only the superficial cells that divide, but the data show that these do so more or less synchronously. The data suggest that a wave of mitosis occurs immediately before the first abrupt increase and that immediately before the second sharp increase another wave of mitosis is completed following the interphase which succeeds the first mitosis. A high mitotic index (12 per cent) has been observed immediately before the first increase but not earlier, and the interpretation proposed is further supported by counts of cell pairs that are seen in certain of the macerates on which the determinations of total cell number are made. Each pair is held together within the wall of the parent cell and the members of the pair are separated by the thin wall formed at the end of mitosis. Each pair is therefore the consequence of an

immediately preceding division. Pairs can be seen only when the first sharp increase in total cell number begins. Thereafter the proportion of these increases sharply as the first increase in total cell number is completed. In due course a phase is reached in which the proportion of pairs remains approximately constant, and this corresponds to the phase of more or less constant total numbers which precedes the second sharp increase in total numbers (see Fig. 2).

Clearly the evidence indicates that at the time of excision all the cells in the explant are at about the same stage with respect to the division cycle, that those that are stimulated to divide all approach the first mitosis, during the initial lag period, at approximately the same rate. Certain observations indicate that the stage from which the progress to mitosis begins in the lag period is early in the pre-DNA synthesis period. Samples from a population have been taken at intervals, the individual explants fixed in ethanol–acetic acid (3 : 1), sectioned at 50μ and Feulgen stained[3]. The density of staining has been measured microspectrophotometrically, and these observations have confirmed those of previous workers[4,5], who showed that immediately after excision, with respect to DNA content, all the cells are in the $2C$ condition and that they attain the $4C$ condition before division occurs. The approximate time of the transition has been analysed in cultures in which tritiated thymidine has been added to the cultures and the proportion of labelled nuclei determined[6] on sections from explants cultured for different periods. The results are shown in Fig. 3, in which the corresponding change in the total number of cells is also shown. It is evident that while in this experimental series the first increase in cell number begins after 24 h, nuclear labelling begins after 12 h but before 24 h. While cell number is increasing from 24–36 h there is little or no increase in the proportion of labelled nuclei, but afterwards this increases again while the total cell number is more or less stationary. The data are not sufficiently critical to provide a basis for the estimation of the duration of the S and G_2 phases preceding the first division wave or of the durations of the three phases during the second division cycle, but they do show that all the cells are in the pre-DNA synthesis phase (early G_1) at the time of excision. This corresponds to the observation that at the beginning of the experimental period the cells are in the $2C$ state with respect to DNA content.

It is significant that nuclear labelling is not observed during the first 12 h. However, an acceleration in respiration is observed immediately transfer to the culture medium is effected[1]. The enhanced respiration no doubt promotes accelerated metabolic activity and it may be supposed that a progress through G_1 begins immediately the cells are transferred to the culture medium. This in turn suggests that at the time of excision the cells are uniformly in early G_1.

ASTROPHYSICS

Resonant Rotation for Venus?

CAN the rotation period of Venus be commensurate with its synodic period? If the rotation period is 243·16 days retrograde, the axis of Venus which points toward the Earth at one inferior conjunction will point toward the Earth at all subsequent inferior conjunctions. This value for the rotation period of Venus lies within the errors of the measured rotation period[1-3]. If the moment of inertia of Venus about this axis is minimal, it is possible that the planet is locked into this synodic commensurability with its permanent bulge or longest axis pointed toward the Earth at each inferior conjunction. In other words, the presence of the Earth may have stabilized the sidereal rotation period of Venus at the value of 243·16 days retrograde. To investigate the stability of such a commensurate spin angular velocity for Venus, we shall use a method similar to that used to determine the stability of the spin angular velocities of Mercury which are commensurate with its orbital angular velocity[4].

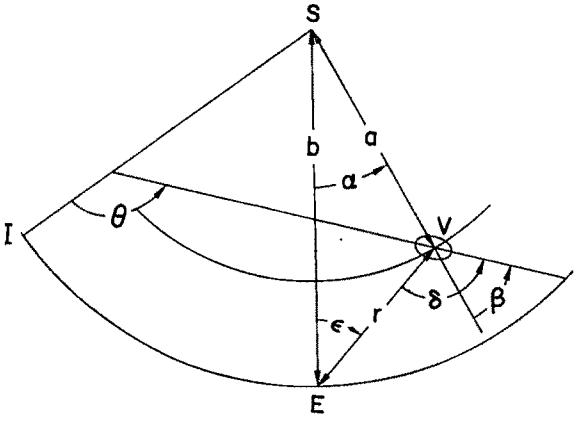

Fig. 1

The orbits of Venus and the Earth are approximated by concentric circles with the spin axis of Venus perpendicular to its orbit plane. It is also assumed that the axis about which the moment of inertia is minimal points approximately toward the Earth at inferior conjunction. Fig. 1 illustrates the angles and co-ordinates involved in the analysis. The points S, E, and V represent, respectively, the Sun, the Earth, and Venus. The semi-major axes of the orbits of Venus and the Earth are denoted by a and b. The distance between the Earth and Venus is r. The long axis of Venus is inclined by an angle θ to the inertial line SI, δ is the angle between the Earth–Venus line and the long axis of Venus, β is the angle between the Sun–Venus line and the long axis, ε is the angle between the Sun and Venus as seen from the Earth, and α is the difference in the heliocentric longitudes of the two planets. In the absence of solar tides, the equation of motion is[5]:

$$C\ddot{\theta}+\frac{3}{2}(B-A)\frac{GM_{\oplus}}{r^3}\sin 2\delta+\frac{3}{2}(B-A)\frac{GM_{\odot}}{a^3}\sin 2\beta=0 \qquad (1)$$

where A, B, and C are the principal moments of inertia in order of increasing magnitude, $M_{\oplus}$ and $M_{\odot}$ are the masses of the Earth and the Sun, and G is the gravitational constant. The condition for a commensurability of the type discussed here is that the average value of $\dot{\beta}$, which we shall denote by $\langle\dot{\beta}\rangle$, be a half-integer multiple of $\dot{\alpha}$. We have the following angular relationships for commensurate motion:

$$\begin{aligned}\dot{\beta}&=-n_v+\dot{\theta}\\ \langle\dot{\beta}\rangle&=p\dot{\alpha}\\ \langle\dot{\theta}\rangle&=n_v+p\dot{\alpha}\end{aligned} \qquad (2)$$

where p is a half integer and n_v is the mean orbital angular velocity of Venus. A retrograde rotation with sidereal period equal to 243·16 days corresponds to $p=-5$. As we wish to investigate the stability of small changes in $\dot{\theta}$ about its mean value $\langle\dot{\theta}\rangle$, we introduce the angular velocity $\dot{\gamma}=\dot{\theta}-\langle\dot{\theta}\rangle$. If conjunction occurs among inertial line SI at the time $t=0$, then:

$$\begin{aligned}\beta&=\gamma+p\alpha\\ \delta&=\gamma+(p+1)\alpha+\varepsilon\end{aligned} \qquad (3)$$

Substituting equations (3) into (1) and averaging over a synodic period, we obtain (see ref. 4):

$$C\ddot{\gamma}+\frac{3}{2}K(p)(B-A)\frac{GM_{\oplus}}{b^3}\sin 2\gamma=0 \qquad (4)$$

where $K(p)$ is determined by numerical integration on an IBM 7094 computer. The values of $K(p)$ for various values of p are listed in Table 1. Perturbations of the orbit of Venus by the Earth also contribute to $K(p)$. However, for the resonance in question ($P=-5$), this contribution is negligible.

The commensurate rotation rates are seen to be stable in the absence of any external torques other than those due to the permanent deformation of Venus from axial symmetry. The resonance will remain stable if the net additional torque ($-T$) satisfies:

$$|T|<\frac{3}{2}K(p)(B-A)\frac{GM_{\oplus}}{b^3} \qquad (5)$$

A solar tidal torque must be acting on Venus. If this were the only significant additional torque, the criterion for stability would be:

$$\frac{B-A}{C}>\frac{4\times10^{-2}}{K(p)Q}=\frac{1{\cdot}6\times10^{-2}}{Q} \qquad (6)$$

for $p=-5$. Here $1/Q$ is the specific dissipation function[6]. Estimates between 10 and 20 for the Earth's tidal effective Q are derived from observation of the secular acceleration of the Moon[6]. These low values may be primarily due to dissipation in shallow seas[7], and therefore may not be applicable to Venus. Estimates of the Q for the Earth's mantle are on the order of several hundred[8]. A stable resonance with a Q of this order for Venus would require a value of $(B-A)/C$ comparable with that of the Moon. It is not at all certain that Venus could maintain such a deformation because the larger surface gravity of Venus would imply greater internal stresses than those supported by the Moon.

Table 1

p	$K(p)$
−0·000	0·908
−0·500	1·479
−1 000	2·857
−1·500	3 831
−2·000	4·311
−2·500	4·394
−3·000	4·204
−3·500	3·851
−4·000	3·417
−4·500	2·958
−5·000	2·513
−5 500	2·001
−6 000	1·735
−6 500	1·417
−7·000	1·147
−7·500	0·921
−8·000	0·734
−8·500	0·582
−9 000	0·460
−9·500	0 360
−10·000	0·282

If Venus had a primordial forward spin, the solar tides could not account for the present retrograde rotation. This has led some authors to propose the existence of other torques on the planet, notably of atmospheric origin (Gold, private communication (1964); MacDonald[6]). As the mass of the Venusian atmosphere is thought to be comparable with that of the Earth's oceans, such proposals seem quite reasonable. If the atmosphere is capable of pushing Venus through the otherwise stable synchronous state of rotation (with respect to the Sun), present control of the rotation of Venus by the Earth is difficult to understand.

In a previous communication[4], we discussed stable resonant spins for a planet in an eccentric orbit. We found that a necessary condition for capture into a resonance was the existence of a significant term in the tidal torque which would damp librations about the commensurate spin value. For Venus a similar condition must be met by the total additional torque T. As yet we have been unable to find any physical basis for the existence of such a term.

A refined measurement of the rotation period of Venus will be awaited with great interest.

Detection of Hydrogen Emission Line 166α in *M*17

The existence of recombination lines of highly excited states of hydrogen is well established through recent radio observations[1,2] of various galactic H II regions. This communication reports the detection and analysis of a new line $n_{167} \rightarrow n_{166}$ (1,424·736 Mc/s) in *M*17, which extends our previous results[1] to lower frequencies. This particular $n \rightarrow n-1$ transition lies closest to the well-known 21-cm hyperfine line of interstellar hydrogen. We also suggest a convenient notation for the various transitions.

Our data were obtained with the Harvard 60-ft. telescope equipped with a cavity maser 10-channel radiometer having a resolution of 80 kc/s. The antenna beamwidth is 52 min of arc, and its aperture efficiency is 0·38 at the frequency of operation. The total noise temperature of the system is approximately 100° K. The maser used in this investigation is essentially the same as that used by Lilley *et al.*[1].

Our profile for *M*17 is shown in Fig. 1. Using our observational results (Table 1), we obtain, in a manner completely analogous to that described by Lilley *et al.*[1], $T_e = 5{,}900 \pm 2{,}400°$ K, where T_e is the computed electron temperature. This result agrees satisfactorily with the previous[1] determination of $6{,}800 \pm 3{,}000°$ K and $5{,}500 \pm 2{,}400°$ K and with Hoglund and Mezger[2], who obtained $4{,}060^{+430}_{-380}$ K.

In Fig. 2 we have plotted all reported values for *M*17 of the observed linewidth versus wave-length of observation. These values fall nearly on a straight line as expected for purely Doppler broadening as suggested in Fig. 2. Thus, our present result agrees with the conclusion arrived at by Lilley *et al.*[1] that the linewidth can be entirely accounted for by thermal and turbulent broadening to $\nu \sim 1{,}420$ Mc/s.

Table 1 Summary of Observational Results

ν (Mc/s) = 1,424	$\Delta\nu_L$ (kc/s) = 200
T_A (°K) = 0·195 ± 0·030	$\Delta\nu_L$ (corrected) = 183 ± 60 (kc/s)
T_L/T_C = 0·83 ± 0·17 per cent	V (km/s) = 20 ± 7

The above quantities are defined in ref. 1.

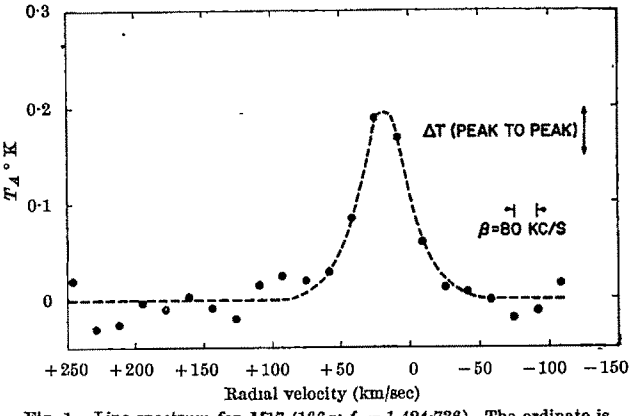

Fig. 1. Line spectrum for *M*17 (166α; f_0 = 1,424·736). The ordinate is antenna temperature. The abscissa is velocity with respect to the local standard of rest

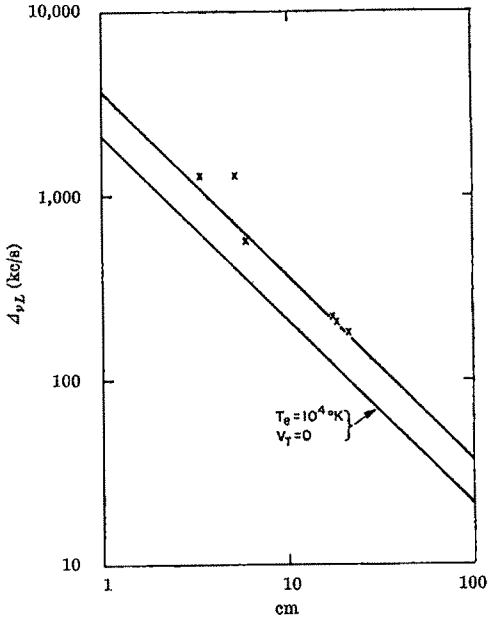

Fig. 2. Plot of linewidth ($\Delta\nu_L$) versus wave-length for all observed $n \rightarrow n-1$ lines in *M*17

We have also observed a region near *W*75 (ref. 3) and have obtained evidence for a line, although the signal-to-noise ratio is not sufficient for quantitative analysis.

To avoid cumbersome notation for future work on lines of excited hydrogen, we suggest a notation widely used in optical spectroscopy. For example, the $n_{167} \rightarrow n_{166}$ transition reported in this communication would be labelled simply 166α. The transition $n_{200} \rightarrow n_{198}$ would be designated 198β. The number represents the principal quantum number of the lower state, and α, β, γ . . . designate respectively transitions of type $n \rightarrow n-1$, $n \rightarrow n-2$, $n \rightarrow n-3$, etc. This notation is consistent with Lyman α (1α), Hβ (2β), etc.

The use of the line 166α (at 1,424 Mc/s) will enable the many hydrogen-line (1,420 Mc/s) systems around the world to examine both ground state and excited hydrogen.

This investigation was supported by the U.S. National Science Foundation.

PHYSICS

Dislocation Velocities

THE purpose of this communication is to discuss the various techniques which have been used to obtain information concerning the velocities of dislocations, and particularly to point out the differences between techniques. In view of these differences, suggestions are offered as to how the various results ought to be interpreted in order to provide the most useful information.

Three techniques have so far been proposed for determining the effect of stress on dislocation velocity. The method of Johnston and Gilman[1] consists of isolating a single dislocation half-loop; locating the positions of its ends by etch-pitting; applying an essentially rectangular stress-pulse of known intensity and duration; re-etching to find the distances which the ends of the half-loop move. The distance moved divided by the pulse duration is then the average velocity associated with the given stress. In a variation of this method first used by Stein and Low[2], fresh dislocations are introduced by scratching the surface of the specimen immediately prior to application of the stress-pulse. After stressing, the specimen is etched and the distance from the scratch to the furthest etch-pit is used in the calculation of average velocity. Finally, as a means of reducing the experimental complexities of these two methods, Guard[3] suggested that in the plastic régime during a simple tension or compression test the cross-head speed of the testing machine be suddenly altered by a substantial amount and the resulting change of flow stress noted; then through an equation relating the plastic strain-rate to the dislocation population and its average velocity, inferences could be made concerning the stress dependence of this velocity.

It is vitally important to recognize that these three methods relate to three totally different physical situations. A dislocation examined by Johnston and Gilman has moved through a crystalline region free from the influences of other dislocations. The factors affecting its motion are only the applied stress and the intrinsic drag of the lattice as modified by impurity content, other point defects, etc. On the other hand, a dislocation observed by Stein and Low is additionally influenced by local variations in the applied stress resulting from the stress fields of the scratch and all of the dislocations adjacent to it. In the experiment of Guard each dislocation contributing to the overall effect is moving 'through' a rather dense array of neighbouring dislocations, and probably experiences many fluctuations of the local stress field as well as entanglement with its neighbours. (If the entire dislocation population were mobile, and everywhere moving with the same velocity, then the preposition 'through' is superseded by 'with' and the following argument is invalid; but it is not likely that these conditions prevail.) Thus the three methods attempt to describe the average response of dislocation velocity to applied stress, for dislocations in three different environments ranging from isolation to conglomeration.

Should the methods then be expected to yield equivalent results? The answer to this question depends on the details of the interactions among the dislocations. For any particular crystal, some indication is given by its macroscopic stress–strain curve. Regions of strain-hardening indicate strong interactions which should produce fundamentally different results in the different situations, whereas regions of easy glide indicate weak interactions and approximately the same results might be expected. However, the answer to this question is really not important.

The real significance of such experiments lies in the fact that they provide part of the basis for quantitative prediction of stress–strain-time behaviour on the macroscopic scale[1,4–6]. This behaviour is obtained by integration under suitable boundary conditions, of a strain-rate relation of the form:

$$\dot{\varepsilon} = \varphi \rho v \qquad (1)$$

Here ε is the plastic strain, and the dot indicates time derivative; φ is an orientation factor which depends on the configuration of dislocations present, and the strain (it may, therefore, be termed a structure factor); ρ is the length of dislocation line per unit volume (also called dislocation density because one of the important measuring techniques related to this quantity is surface etch-pitting to determine the number of line intersections per unit area); and v is the average dislocation velocity.

The integration of equation (1) involves specification of the forms of φ, ρ and v. It has been usual to assume that φ is a constant, or that changes of φ have a negligible effect on the final results. As regards ρ, experiments indicate that this is approximately a linear function of plastic strain:

$$\rho = \rho_0 + \alpha\varepsilon \qquad (2)$$

The earliest velocity–stress relations were either fitted to the empirical formula:

$$v = (\tau/\tau_0)^m \qquad (3)$$

or to the relation derived by Gilman[7]:

$$v = v^* \exp\{-D/\tau\} \qquad (4)$$

These formulae each contain two parameters (τ_0, m and v^*, D) which can be adjusted to provide a best fit for the data. Integration of equation (1) based on the other relations has been quite successful in providing quantitative descriptions of macroscopic phenomena in the small-strain, short-time régime. For long times a mechanism of ageing must be included; for large strains, a description of hardening.

Some investigators have described hardening in terms of an 'effective stress' experienced by the dislocations. The reasoning is that long-range stress fields will develop as the dislocation population increases, and that a 'back stress' will tend to impede the progress of moving dislocations. The average dislocation velocity is then supposedly governed by the effective stress. That is, in equations (3) or (4) τ is replaced by this effective stress. However, such analyses must always conclude that after yielding this effective stress simply equals the yield stress. Thus any hardening introduced in this manner is essentially empirical. Moreover, the concept of effective stress is inimical to the equilibrium requirement for the spatial average stress to equal the applied stress.

Chen, Gilman and Head[8] provide a more satisfying approach to the mechanism and description of hardening. They have investigated the effect of a fluctuating stress field on the average velocity of a moving dislocation, assuming that its instantaneous velocity is given by equation (4). For sinusoidal fluctuation of τ about a mean value equal to the applied stress, they show that the average velocity is smaller than the velocity obtained by simply using the applied stress in equation (4). The reason is that more time is lost by the dislocation in traversing the low-stress regions than is gained in the high-stress regions. On this basis it seems sensible to discuss an 'effective drag parameter', or 'effective stress exponent' if relation (3) is being used, rather than conceptually to violate equilibrium with the notion of an 'effective stress'.

At this point the argument may seem entirely semantic, but there is an important advantage to be gained by thinking of D or m (and indeed possibly even v^* or τ_0) as functional quantities rather than as constants. This relates to the method of Guard[3] which has received considerable attention[9–14], particularly during the past year. Considerable effort has been expended in relating the results obtained using this method to those of the other two methods. The fact is that this technique is particularly well suited for

investigating the dependence of (at least one of) the velocity-stress parameters on strain and strain-rate.

The data available clearly indicate that dislocation velocities are dependent on factors other than stress. Even for relatively strain-free crystals the concentration of certain point defects seems to be very influential. Certainly dislocation interactions affect average velocity at some stage of the deformation process and hence the velocity relation must be related somehow to strain. More generally it can be asserted that dislocation velocity is influenced by stress and structure. The term structure is intended to be descriptive of crystalline imperfection, and is somewhat analogous to entropy. Temperature also influences the velocity relation, but so far there is no experimental evidence to indicate whether or not any influence is expected by such variables as strain-rate, hydrostatic pressure, etc.

In summary, there is no reason to believe that dislocation velocities in a given material are determined solely by the resolved shear stress. Investigation of velocity dependence on other appropriate parameters may serve to delineate the true functional form of the velocity relation. This would provide greater insight into the mechanism governing plastic flow and a better quantitative description of the process.

A New Method for determining Surface Densities by Evaluation of the Decrease in Concentration of Single Stationary Drops

Surface densities can be determined from the decrease in concentration and the estimated total area of a large amount of bubbles or drops made to pass through a solution[1]: this method is not accurate since the amount of substance adsorbed by the bubbles or drops is dependent on the hydrodynamics of the system.

An alternative method is now suggested, by which surface densities can be determined directly. The method is based on the fact that adsorption on to the surface of a single drop consisting of a solution of a sparingly soluble substance may lower considerably the original solution concentration. In this method, a drop of known volume and surface area with an initial concentration c_1 is formed, and the surface tension is determined after equilibrium is reached. The final bulk concentration c_2 will be lower than the initial concentration c_1, as solute is adsorbed at the surface. The final bulk concentration c_2 can be determined by comparing the equilibrium surface tension value of the drop with surface tension-concentration data determined by any other suitable method in which adsorption on to the surface does not modify appreciably the bulk concentration. Garner and Garfias[2] have shown that reliable surface tension-concentration data can be obtained from the dimensions of a small air bubble immersed in a large volume of solution.

If it is assumed that all the adsorption of the solute is confined to a superficial layer one molecule thick, and that the concentration in the bulk of the drop is constant right up to the superficial layer, then the surface density is the difference per unit area between the initial and final amount of solute present in the bulk of the drop, as given by the equation:

$$n = \frac{V(c_1 - c_2)}{S}$$

where n is the surface density in g moles/cm^2; V, the drop volume in cm^3; c_1 and c_2, initial and final concentration in g moles/cm^3; and S, the drop surface area in cm^2.

It can be shown that surface adsorption can lower considerably the concentration of drops, by considering a drop of undecanoic acid solution, which at equilibrium has a final concentration c_2 of $1{\cdot}5 \times 10^{-8}$ moles/cm^3. For a drop with a volume of 0·020 ml. and a surface area of 0·30 cm^2 the amount of solute contained in the bulk of the drop is 3×10^{-10} g moles. Dervichian[3] has reported that the equilibrium film has a density of 4×10^{-10} g moles/cm^2, so there are also $1{\cdot}2 \times 10^{-10}$ g moles adsorbed at the surface of the drop. The total amount of solute present is therefore the sum of that in the bulk and in the surface, that is, $4{\cdot}2 \times 10^{-10}$ g moles, which would require that initially the drop should have been formed with a solution containing $2{\cdot}1 \times 10^{-8}$ g moles/cm^3 of undecanoic acid; in other words, for this particular example, the concentration is 40 per cent lower after surface adsorption has taken place.

Besides the fact that the suggested method is confined to the investigation of the surface densities of a few sparingly soluble substances, there is an additional restriction imposed by the nature of the method. In effect, surface densities cannot be determined for all ranges of concentration: the maximum concentration for which the surface density may be determined by this method corresponds to that in which the total amount of solute (bulk plus surface) per unit volume gives the saturation concentration.

Experiments at liquid–air and liquid–liquid interfaces are being conducted by one of the authors (F. J. G.) and will soon be reported.

GEOPHYSICS

Time Variations of Geomagnetic *H* and *D* at Disturbed Stations

The cylindrical co-ordinate system, defined by the components H, D and Z, used to describe the geomagnetic field brings some noteworthy consequences when going from the field to its time gradients. Although of a quite elementary geometrical nature these effects are sometimes overlooked in magnetic cartography and research work.

The use of the direction co-ordinate D, determined by the field itself, is due to practical reasons: it is the direction of a compass needle. H and D completely describe the horizontal part of the field, as do X and Y or any other pair of horizontal magnetic 'elements'.

Fig. 1 shows the prevalent H and D as determined at a certain station at a certain time. We further have the disturbance field P, α due to a crust anomaly. We could of course easily produce this disturbance ourselves by placing a magnet in a fixed position close to the instruments. We further assume that we know the 'normal' field H_n, D_n which would prevail if P did not exist.

Transforming to geographical north and east components, we obtain:

$$X = H \cos D \qquad X_n = H_n \cos D_n$$
$$Y = H \sin D \qquad Y_n = H_n \sin D_n$$

Since P,α are constant, the time variations in the xy-frame are equal:

$$\dot{X}=\dot{X}_n$$
$$\dot{Y}=\dot{Y}_n$$

This leads to the following expressions for the 'normal' time variations in terms of those observed:

$$\dot{D}_n=\frac{H\dot{D}}{H_n}\cos\,(D_n-D)-3438\,\frac{\dot{H}}{H_n}\sin\,(D_n-D)$$

$$\dot{H}_n=\frac{H\dot{D}}{3438}\sin\,(D_n-D)+\dot{H}\cos\,(D_n-D)$$

where $\dot{D}_n$ and $\dot{D}$ are expressed in minutes of arc per time unit. As can be seen the change in one 'normal' component is a function of $\dot{D}$ as well as $\dot{H}$.

Let us apply these formulae to the following practical case, approximately valid for the Kiruna Observatory 1954–55:

$H=11{,}000\gamma$	$D=-7°$ (observed)
$H_n=12{,}100\gamma$	$D_n=+1°$ (estimated)
$\dot{H}=+2\gamma$/year	$\dot{D}=+9'$/year (observed)

H_n and D_n were estimated from a magnetic chart. Inserting these values in the foregoing equations yields:

$$\dot{H}_n=+6\gamma\text{/year}\qquad \dot{D}_n=+8{\cdot}1'\text{/year}$$

These values are considerably different from the observed values.

The observed values H, D indicate a significant magnetic anomaly, that is, deviation from the 'normal' field, in the sense that we will get a similar deviation whichever pair of horizontal components we use.

The pair $\dot{H}$, $\dot{D}$ does not constitute an anomalous annual change of significance. The anomaly is only a geometrical effect. In the north-east system we obtain:

$$\dot{X}=\dot{X}_n=5.5\ \gamma\text{/year}$$
$$\dot{Y}=\dot{Y}_n=28.6\ \gamma\text{/year}$$

Physically, the results given here are only an illustration of the well-known fact that there is little or no correlation between small-scale field anomalies (with sources in the crust) and the anomalies of the secular variation (with sources in the core).

The time variations of the disturbance field P,α which would make $\dot{X}\neq\dot{X}_n$, $\dot{Y}\neq\dot{Y}_n$, are generally much smaller than the secular variation and difficult to detect in short time spans. This stability of the thermoremanent magnetization (and other kinds of rock magnetism) is essential for the archaeomagnetic and palaeomagnetic research.

In magnetic cartography no deeper meaning should be attached to local anomalies in $\dot{H}$ and $\dot{D}$ without a closer look. As a supplement isoporic maps based on $\dot{X}$ and $\dot{Y}$ are recommended. The field stations, including the 'secular stations', providing most of the data for magnetic charts are often disturbed, simply because it is almost impossible to find undisturbed stations in some areas.

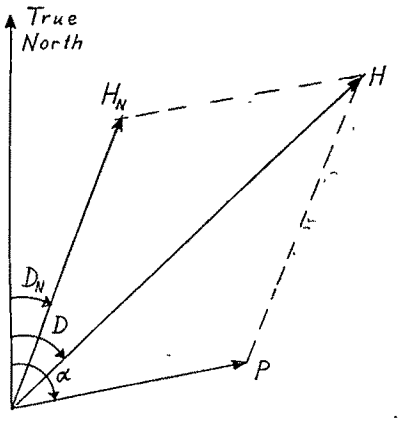

Fig 1

The previous discussion is of course applicable to all time variations, such as storms, diurnal and lunar variations, bays, pulsations, sudden commencements. For example, before attributing physical significance to the amplitudes in H and D of Sq at a magnetic observatory it may be worth while to check (by means of observatory data and magnetic charts) whether or not the field is under influence of a local anomaly. $Sq(H)$ and $Sq(D)$ may differ considerably from $Sq(H_n)$ and $Sq(D_n)$. It is always safer to work in X and Y. Another pair of useful horizontal components are Hgm, Dgm where Hgm is the component in the direction of geomagnetic north.

It is usual practice (with important exceptions) to locate magnetic observatories in areas which are as free as possible from local disturbances. This is often ascertained by means of a local survey. If the field gradients are sufficiently small the site is considered suitable. There may, however, be larger, regional anomalies which are not detected in this way. In this case the recorded 'disturbed' values $\dot{H}$, $\dot{D}$ may be representative for a fairly large area. Still, they do not necessarily indicate a real anomaly in the time variations studied.

A synoptic study of the amount of local disturbance at the magnetic observatories may be helpful to users of magnetic data. The whole discussion is, of course, somewhat obscured by the vagueness of such conceptions as 'normal field' and 'disturbance'.

GEOLOGY

The Malvern Lower Cambrian Strata

IN a recent communication R. St. John Lambert and D. C. Rex[1] imply that the palaeontological evidence is insufficient for any claim to be made that Lower Cambrian strata are exposed in the Malvern Hills. Whereas there is some doubt concerning the presence there of Middle Cambrian rocks, there is little doubt about the existence of Lower Cambrian. The earliest fossiliferous strata in Shropshire, which occur above the Wrekin Quartzite but at least 450 ft. below the Olenellid *Callavia* Limestone, were described by Cobbold[2] as yielding two of the brachiopod species described by Matley[3] from the Malvern Quartzite of the Malverns, namely, *Micromitra* (*Paterina*) *phillipsi* (Holl) [olim *Kutorgina cingulata* auct.] and *Obolella groomi* Matley[4]. Later, a third brachiopod species known elsewhere only in the Shropshire *O. groomi* fauna, *Micromitra* (*Paterina*) *rhodesi* Cobbold, was collected by H. F. Metcalfe from the Malvern Quartzite in association with the previously recorded forms[5]. It is significant to learn that the "last major isotopic event in the Malvernian occurred 590 ± 20 m.y. ago"[1], for this has an important bearing on the problem of the date of the base of the Cambrian. It would be of even greater interest to learn the isotopic age of the palaeontologically dated Lower Cambrian Comley Sandstone glauconitic rocks from Shropshire which are being investigated by the Oxford group.

Volcanic Chronology of Lanzarote (Canary Islands)

The relative or absolute chronology of Late Tertiary and Quaternary events in the Eastern Canary Islands is mostly unknown. Pacheco[1] and Hausen[2] both attribute the cinder cones and olivine basalts of the central volcanic region of Lanzarote to the Quaternary on general grounds; the preservation and freshness of form. The northern and southern uplands of Famara (671 m) and Ajaches (561 m), built of weathered lavas and pyroclastics with deep valley dissection, are similarly attributed to the early Tertiary; a formation termed the Tableland Series by Hausen and, in Ajaches, the Ajaches Volcanic Series by Driscoll *et al.*[3].

To elucidate the volcanic chronology a number of systematic themes were followed and linked by field mapping at the scale 1 : 25,000. Foremost among these was the use of an established raised beach succession to provide a broad grouping and relative dating of the volcanics where they outcropped at the coast. Within this grouping, field mapping reveals a more complex picture not discussed here.

Zeuner's raised beach records for the eastern Canaries lack sections, textual discussion and has few sites[4]. It was not used in this investigation. A raised beach succession reported by Driscoll for the Tertiary Ajaches area of south Lanzarote probably relates to Quaternary eustatic shifts of sea level. Platforms and marine deposits at 55, 35, 23–25, 15, 6 and 1 m, and a shore platform are described. Possible marine erosion levels at 200 m and 300 m were suspected. I have made an attempt to extend this sequence to the entire island.

The 55-m level appeared morphologically flanking the Tableland Series outcrop in the low central region of the island and on the eastern side of the Famara Upland. Blocks of crystalline limestone ejected from more recent volcanoes may represent the shoreline and its deposits north-east of Tinajo.

The 15-m level appears as a cliff line without deposits cut into lavas from Mt. Teneza and buried by later lavas. In the Ajaches area the beach overlies lavas from Mt. Roja, the West Coast Basalts of Driscoll and not the Tableland Series as assumed by Hausen and Pacheco. The 25-m beach reported in Ajaches by Driscoll refers to the surface of terrestrial deposits; the marine beach is 8–10 m. lower. Marine and terrestrial deposits are probably above the former intertidal zone, as is usual on this coast, and the old sea level would appear to be near 15–17 m. Relict potholes and rolled boulders appear at this height. A marine conglomerate at 8–9 m covered by lava from Atalaya de Femés at Berrugo probably relates to the 15-m level. It has a similar fauna but lacks corals. Shingle bands at various heights on the cliffs of the east Ajaches coastline are poorly rounded, lack marine fauna and are interpreted as interbedded gravels with the Ajaches Volcanic Series, unrelated to Quaternary sea level.

The 6-m and the 1-m beaches form the best basis for the broad grouping of volcanoes and lava fields (Fig. 1). The 6-m level is extensively found: a hard limestone and conglomerate with a warm water fauna, particularly *Strombus bubonius*, a gastropod now absent from the Canaries. On the calm south-east facing (Sotavento) coast the beach is depositional in embayments, but on lava-flow headlands it often lacks a precise morphology. Limestone and small shells impregnate angular basal scoria of the sub-horizontal laval flows, frequently appearing to be older than the solid lava just above, but there is no sign of contact metamorphism. In the Ajaches area, lavas from Atalaya de Femés reach the sea at Janubio and Berrugo where they are older than the 6-m beach. The 1-m beach deposits are less calcareous, virtually recent in fauna and parallel present beach contours. Erosionally the 1-m level intercliffs 6-m deposits while north of Arrecife (east coast) a deep beach section showed the 6-m and 1-m deposits separated by a rotlehm[5] extending below sea level. A rotlehm is often found below the 1-m conglomerate where it occurs alone.

Above 55 m, no marine deposits are found. The erosional levels of *c.* 200 m and 300 m fail to appear in the Famara. However, Mt. Ubique (308 m), a cone some distance south of the Famara, the only preserved cone of the Tableland Series, is strongly cliffed on the south-east flank in contrast to its other smoothly aggraded slopes. This may indicate marine action to its foot at *c.* 150–160 m although the old abrasion platform is covered by later lavas.

The age and presence of this cone isolated in the central volcanic region indicate that this low region, with small Tableland Series exposures, is due to regional inequality of the Tertiary eruptions, and not to later faulting forming a 'tectonic graben' (Hausen). Similarly there is no field evidence for the faults invoked for the Famara and Ajaches escarpments; indeed, there are no faults in any exposures of the Tableland Series. Pacheco's thesis of long continued and strong erosion from the west must still stand. On the Famara Upland field mapping shows that the gently rising plateaux culminating in rocky outcrops of columnar basalt are the sub-original lava

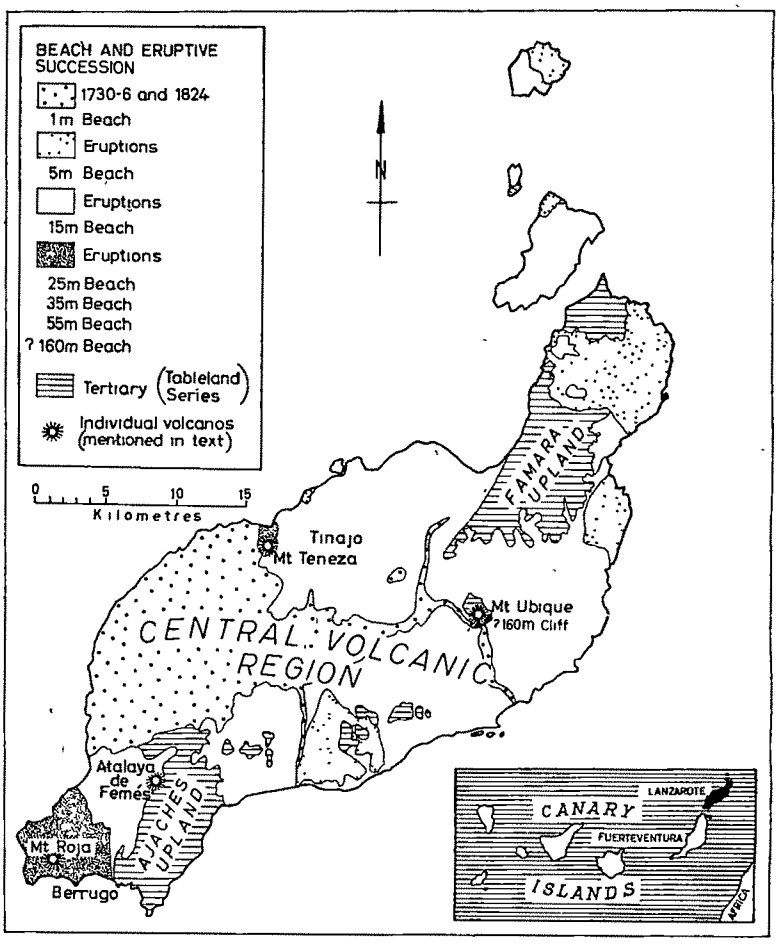

Fig. 1. Map of the volcanic chronology of Lanzarote based on the raised beach succession

fields and throat fills of old volcanoes. Scoria and lapilli are seen dipping off the old necks. The deep radiating barrancos emphasize the original topography and are a true consequent drainage pattern. Many have since been blocked and partly filled by lavas from shield volcanoes, at least one of which is younger than the 15-m stage. In the more closely dissected Ajaches area this is less easy to demonstrate, but throat plugs and lapilli cone structures are found. Benches at high levels here appear to be dependent on structure.

The eruptive nature of the Tertiary volcanics is very similar to that of the Quaternary volcanics of the central region, a fact noted by Hartung[6]. They are not the fissure eruptions envisaged by Pacheco, nor do they merit the name 'Tableland', being in no way similar to the Antrim or Deccan plateaux basalts. The broad grouping revealed by Fig. 1 shows that the lavas between the 15-m and 5-m stages were the most extensive. While Quaternary vulcanism is known in the Tertiary Uplands and particularly the Famara, its reiterated manifestations are in the low central region. The eruptions between the 5-m and 1-m stages are less extensive, but this may merely reflect a shorter time interval. A linear pattern linking eruptions within and between these groups can be seen. The historic eruptions of 1730–36 and 1829 are unaffected by raised beaches.

There is no certain Quaternary vulcanism anterior to the 55-m stage and most of it post-dates the 15-m stage. The 25-m and 35-m stages recorded for Los Ajaches (and Fuerteventura, see below) are entirely missing; they are probably buried. The apparent break in vulcanism from the early Later Tertiary to the Middle Pleistocene may be in part illusionary due to a later burial by lavas, but it seems unlikely in view of the preservation of cones of both ages only partly modified. Since the Middle Pleistocene, successively younger lavas have eliminated the higher beaches, providing clear evidence of the progressive youthfulness with decreasing height of the raised beach successions. This constitutes an important local proof that the lower beaches are younger, a proof independent of the concept of 'intercliffing'.

The 160-m level and the raised beach series below 55 m can be tentatively correlated with similar successions on the west coast of Fuerteventura[7] and Morocco[8]. Cliff-foot heights and faunal associations provide the basis. The sequence may date back to the end of the lower Pleistocene (55 m = Sicilian following Lecointre[8]) while the 150–160 m level recorded on Mt. Ubique may date to the Lower Pleistocene or Late Pliocene (= Villafranchian). In conjunction with preservation of form and sub-original topography it suggests an age closer to Miocene or Pliocene for the upper succession of the Tableland Series rather than the early Tertiary and post-Eocene ages of Hausen and Pacheco. The presence of the cone Mt. Ubique seems to preclude any higher transgressions. No interbedded marine deposits are known within the Tableland Series.

The tectonic stability of the region which these tentative correlations imply is supported in the field. Spanish survey marks are inadequate for precise levelling and variations in exposure prohibit the detection of slight changes of level, but there is no sensible variation on the 6-m or 1-m beaches. The 55-m beach encircling Los Ajaches and morphologically present elsewhere is a major stage (40 m–65 m), but nowhere is there any sign of disturbance. The absence of evidence of faults in either the Tertiary or Quaternary formations seems to preclude large-scale tectonic activity in these periods despite extensive vulcanism although minor seismic activity associated with imminent eruptions is not unknown[9]. Such stability is noteworthy so close to a continental margin and particularly in view of attempts to see North African structural lineaments in the Canaries with the possible tectonic implications of this. While the Casablanca area is a reputedly stable part of the Moroccan Meseta, many parts of the Atlas owe their origins to Quaternary tectonics. The deep seas (4,500 ft.) between the islands and Africa may indicate a separation from the African basement and partial insulation from tectonically active zones.

This succession, established for Lanzarote, may serve as a useful point of reference in studies on the more vulcanologically complex islands of the Central and Western Canaries.

I thank Dr. S. Gregory for reading critically the draft of this manuscript. The work is being carried out on a Department of Scientific and Industrial Research studentship which is gratefully acknowledged.

METALLURGY

Strain Hardening in Fatigue

Fractographic studies[1–3] using optical and electron microscopy have shown that, for many metals, high-strain fatigue endurance is determined by crack propagation of the type designated stage II by Forsyth[4]. This is contrary to the statistical argument put forward by Gittus[5] and the dislocation intersection model of Gilman[6], neither of which is in accord with fractographic evidence.

In a recent theory[7], Grosskreutz has related high-strain fatigue endurance to the ductility at fracture in a tensile test, as proposed by Coffin[8], and the strain-hardening coefficient, n.

We picture crack propagation occurring by plastic flow away from the crack tip during the tensile part of a cycle and this flow is not completely reversed by compression. The deformation causes strain hardening ahead of the advancing crack and inhibits plastic flow in the subsequent cycle. Continued crack propagation can only occur if further strain, and thus strain hardening, occurs at the crack tip. We therefore anticipate a continuous increase in strain hardening from the crack nucleus to the crack position at final fracture.

A technique reported by Williams[9] has been used to measure microhardness on the fracture surface and has shown that a continuous increase in strain hardening exists. Specimens of type 316 steel which failed with lives between 5×10^2 and 7×10^5 cycles were mounted in a transparent medium which was polished away parallel to the fracture surface. When the fracture surface was reached, islands of metal were exposed (Fig. 1), these being taper sections of the particular local feature. It has been verified that the ripples present are of the form reported by Laird and Smith[1]. Microhardness indentations were placed on regions of high taper magnification. The hardness values obtained thus give a measure of the condition very close to the fracture face; this cannot be done directly on fracture faces or on longitudinal sections. Indentations were made using the Reichart microhardness tester loaded at 31 g. A typical result is shown in Fig. 2 with error bars drawn at one standard deviation; note that the annealed material and material in the necked down region of a fractured tensile test piece have diamond indentation ocular readings of 106 and 84, respectively. Measurements in the gauge portion indicate that some progressive hardening occurs during testing, but this is a second-order effect compared with the local hardening at the fracture face.

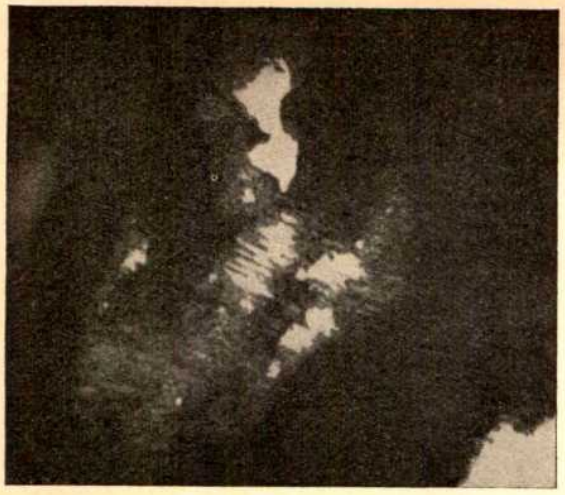

Fig. 1. Islands of metal showing fracture surface ripples revealed by taper sectioning. Specimen subjected to high strain fatigue. Failed in 12,435 cycles. (*c.* × 800)

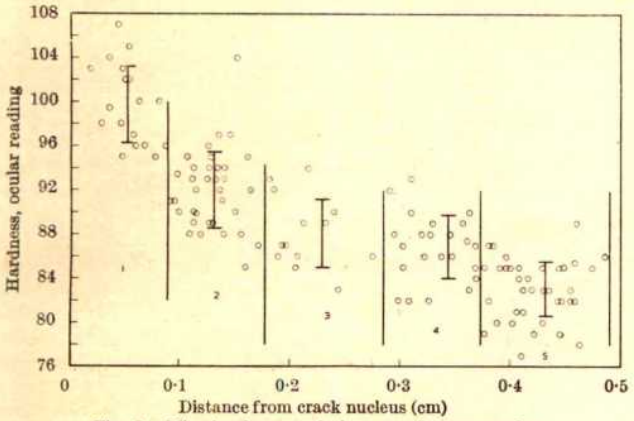

Fig. 2. Microhardness variation over fracture surface

It is believed that a continuous increase of strain hardening during crack initiation and propagation is a common feature during testing of ductile metals, even when 10^7 or more cycles are required for failure. It is also suggested that the foregoing results indicate that strain hardening to some level appropriate to the ultimate tensile strength is not necessary before a crack can advance.

CHEMISTRY

Partition Isotherms and the Mixed Second Virial Coefficient

In a recent publication[1] Sewell and Stock have presented their results for the effect of an inert gas, nitrogen, on the solubility of carbon tetrachloride in non-volatile liquids used as stationary phases in gas-liquid chromatography. Although not stated, it is to be understood that the method is based on the original proposals and work of Freeguard[2] and Stock, and it is the aim of this publication to direct attention to the consistency of Freeguard's results and to indicate a method whereby the later results may be used to evaluate B_{12}, the second virial coefficient that accounts for the interactions between unlike molecules of the mixed gases.

To avoid confusion we adopt the nomenclature of the previous publication[1]; thus the fugacity, p_2^*, of the pure vapour at a pressure p_2 is given by:

$$\ln p_2^* = \ln p_2 + B_{22} \cdot p_2/RT$$

where B_{22} is the second virial coefficient of the pure vapour. The activity of the vapour is given by the ratio of the fugacity at the pressure p_2 to that of the saturated vapour at the temperature T.

Therefore

$$\ln a_2 = \ln p_2^*/p_2^{*0} = \ln p_2/p_2^0 - B_{22}(p_2^0 - p_2)/RT \quad (1)$$

where a_2 is the activity of the vapour and p_2^0 the saturated vapour pressure. Let x_2 be the mole fraction solubility of the vapour in the non-volatile solvent and γ_2 be the solute activity coefficient at this concentration. Since vapour and solute are in thermodynamic equilibrium, it follows that:

$$\ln a_2 = \ln x_2\gamma_2 = \ln p_2/p_2^0 - B_{22}(p_2^0 - p_2)/RT \quad (2)$$

In the presence of nitrogen, when P is the total pressure and $P-p_2$ its partial pressure, we have:

$$\ln x_2'\gamma_2' = \ln p_2/p_2^0 + P[B_{22} - (1-y)^2(B_{11} - 2B_{12} + B_{22})]/RT - B_{22}p_2^0/RT \quad (3)$$

where x_2' is the new mole fraction solubility of the vapour, γ_2' the corresponding value of the activity coefficient and B_{11} the second virial coefficient of nitrogen. We note that the situation has been simplified by the assumption that the effect of applied pressure on γ_2 is negligibly small when P assumes values the maximum of which are not very much greater than 1 atmosphere. Adopting the assumption[2] (but with some reservation) that for y, the mole fraction of the solute in the gas phase, we may write $y = p_2/P$, and subtracting equation (2) from equation (3):

$$\ln x_2'\gamma_2' - \ln x_2\gamma_2 = P[B_{22} - (1-p_2/P)^2(B_{11} - 2B_{12} + B_{22})]/RT - p_2B_{22}/RT \quad (4)$$

from which

$$RT(\ln x_2'\gamma_2' - \ln x_2\gamma_2) = B_{12}[2P\,(1-p_2/P)^2] - B_{11}[P\,(1-p_2/P)^2] + B_{22}[p_2(1-p_2/P)] \quad (5)$$

From the results of a previous investigation[3] it may be shown that over a wide range of concentration ($x_2 = 0$ to $x_2 = 0{\cdot}45$)

$$\ln x_2\gamma_2 = A \ln x_2 + C \quad (6)$$

where A and C are constants characteristic of the solvent (we use A and C for dinonyl phthalate and A' and C' for squalane).

Therefore

$$A.RT(\ln x_2' - \ln x_2) = \mathrm{f}(B,p_2,P.) \quad (7)$$

where $\mathrm{f}(B,p_2,P.)$ is used as an abbreviation for the right-hand side of (5).

If we consider the equilibrium condition for a second and different non-volatile liquid in the same atmosphere, we have

$$A'.RT(\ln x_{22}' - \ln x_{22}) = \mathrm{f}(B,p_2,P.) \quad (8)$$

where x_{22} and x_{22}' are the initial and final mole fraction vapour solubilities, respectively.

Therefore

$$A \ln(x_2'/x_2) = A' \ln(x_{22}'/x_{22}) \quad (9)$$

Furthermore, if $A = A'$ (which is almost exactly the case for the dinonyl phthalate/carbon tetrachloride and squalane/carbon tetrachloride systems), then

$$x_2'/x_2 = x_{22}'/x_{22} \quad (10)$$

It is this relationship (10) that has been demonstrated[2] to hold over a range of pressure to $P = 22$ cm mercury by the technique as later described by Sewell and Stock but

using an apparatus with less efficient mixing; it was for this reason that the results were considered of insufficient precision for the calculation of B_{12}. However, since in all cases $x_2' < x_2$, a negative value of B_{12} was indicated, in keeping with the predictions of the theory of corresponding states.

To calculate a value of B_{12} from all data[4] equation (7) was used in conjunction with Coggan's[5] multi-fit programme using the *Atlas* I computer at the University of Manchester. In terms of the criterion

$$\Sigma(x_2^{\text{observed}} - x_2^{\text{calculated}})^2$$

the best value for each set of data, namely -997 for dinonyl phthalate and -540 for squalane, was approximately three times better than the corresponding states value of -158. The value -790 which is five times the theoretical value of B_{12} appears to give a reasonable fit to both systems, particularly when $P-p_2$ approaches 1 atm., and is therefore suggested for calculations in gas-liquid chromatography. There is evidence, however, that structural alterations in the mathematical model would enable a very much more accurate fit of data to be made. The theoretical implications of such a model are at present being examined by Dr. Coggan and myself.

I thank Dr. G. C. Coggan for his help in connexion with the data processing and Mr. P. A. Sewell and Dr. R. Stock for making all their results available.

Joule–Thomson Effect: Non-ideality and Association

It is generally asserted in text-books on thermodynamics and the properties of gases that the Joule–Thomson effect demonstrates conclusively that real gases are non-ideal. This is indeed the case, but not in the sense that usually seems to be understood.

The Joule–Thomson effect is a measure of the extent to which, at constant pressure, the volume of a fixed mass of gas fails to be strictly proportional to the absolute temperature. Such departures from the relation $pV \propto T$ occur in: (i) non-ideal gases in which there is no chemical reaction; (ii) ideal quantum gases at very low temperatures; (iii) associating gases (ideal and non-ideal).

Case (ii) has been considered briefly by Landsberg[1]. The purpose of the present communication is to emphasize the relevance of case (iii) (exemplified by the large[2] Joule–Thomson effect exhibited in experiments[3] conducted for another purpose on the associating gas $2NO_2 \rightleftharpoons N_2O_4$); and to point out that, even when the possibility of association is taken into account, it is still possible to use experimental observations on the Joule–Thomson effect as one of the sources of compelling evidence of non-ideality.

Now whereas for inert non-ideal gases there may be either a decrease or an increase in temperature, in an ideal associating gas the Joule–Thomson expansion always leads to a decrease in temperature. That is, $(\partial T/\partial p)_H = -(\partial H/\partial p)_T/C_p$ is always positive (but, provided that a dimer is one of the associated species present, resembles the value for an inert non-ideal gas in tending to a non-zero limit at low pressures). For increase in pressure at constant temperature leads to increased association, and therefore, since enthalpies of dissociation are positive, to decrease in H. Thus, $(\partial H/\partial p)_T$ for an ideal associating gas is always negative, which implies that $(\partial T/\partial p)_H$ is always positive.

It is found from experiment that in certain cases $(\partial T/\partial p)_H$ is negative, as for hydrogen and helium at room temperature and atmospheric pressure, which compels the conclusion that these systems are non-ideal, and cannot be ideal associating gases. That is: the Joule–Thomson effect does not of itself demonstrate non-ideality (as distinct from association); but inversion of the Joule–Thomson effect does.

This conclusion is akin to one concerning empirical equations of state. If at low pressures an expression $pV = RT + Bp$ is found to apply, a negative value of B might be attributable to association, to non-ideality, or to both together; but a positive value of B cannot occur for an ideal associating gas, and so is conclusive proof of non-ideality.

The point considered here is one more example of similarities in the effects of non-ideality and of chemical reaction (compare, for example, "deviations from Nernst's distribution law"). It should be emphasized that in particular instances, as indicated here, it is possible to show conclusively that the system considered is non-ideal.

I thank Prof. F. Gray for valuable discussion of these matters. This communication was prepared during the tenure of the Edward A. Deeds fellowship of Queen's College, Dundee.

Effect of Interstitial Atoms on a Lattice-vacancy Diffusional Process

An investigation has been made of the mechanism of diffusion of chromium into iron–carbon systems over the temperature range 950°–1,265° C. At temperatures above 825° C, the diffusional mechanism of chromium into iron is complicated by a change in crystal structure from a body-centred cubic lattice (α-phase) to a face-centred lattice (γ-phase). At low concentrations of carbon, a lattice-vacancy diffusional mechanism has been postulated, and a moving boundary model set up to represent this condition[1]. The results have confirmed that at concentrations of carbon of less than 0·16 per cent only lattice-vacancy diffusion was effective. At concentrations of carbon above this, the interstitial atoms hinder diffusion.

This communication presents results illustrating this effect for concentrations of carbon up to 1 per cent (Table 1).

Fig. 1, a plot of $\dfrac{\text{diffusivity of chromium in iron } (\gamma\text{-phase})}{\text{diffusivity of chromium in iron } (\alpha\text{-phase})}$ versus concentration of carbon, shows that for concentrations of carbon up to 0·16 per cent this ratio is independent

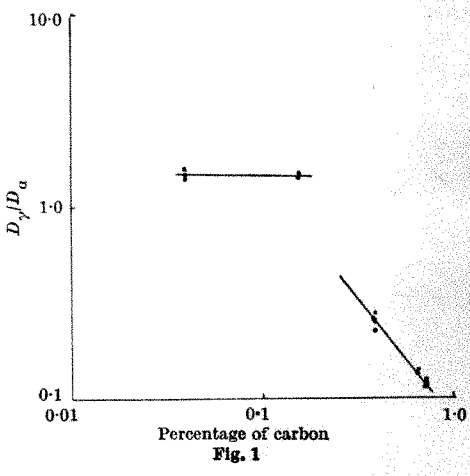

Fig. 1

Table 1

of concentration of carbon as predicted by the model. At higher concentrations of carbon, however, the ratio $\frac{D_\gamma}{D_\alpha}$ is reduced tenfold and is inversely proportional to the concentration of carbon. This indicates that the interstitial diffusion mechanism is now controlling, the effect of the carbon atoms being more pronounced on the face-centred cubic lattice as expected.

Contact Angles of Liquids on Organic Solids

The interfacial tensions between a solid surface (S), a liquid (L) and its vapour (V) can be related as follows[1]:

$$\gamma_{SL} = \gamma_{SV} + \gamma_{LV} - 2\varphi\sqrt{\gamma_{SV}\gamma_{LV}} \quad (1)$$

where the interaction parameter φ is virtually unity for intermolecular forces of dispersion type but rather less than unity for immiscible phases in general. When combined with Young's equation[2]:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV}\cos\theta \quad (2)$$

the result is:

$$\cos\theta = 2\varphi\sqrt{\frac{\gamma_{SV}}{\gamma_{LV}}} - 1 \quad (3)$$

While this is broadly in accordance with Zisman's well-established empirical relationship[3] for low-energy substrates, it fails to account for its rectilinear form.

It seems likely that the curvature implied in equation (3) arises through failure to recognize that low-energy solid surfaces can deform appreciably at an interfacial boundary[4] (Fig. 1).

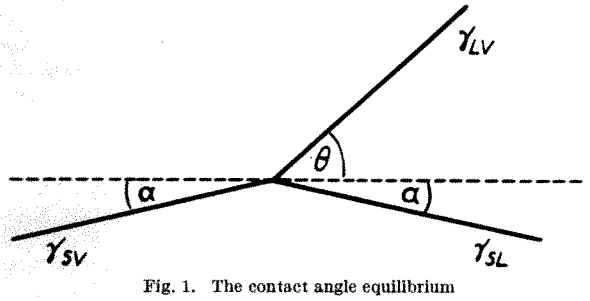

Fig. 1. The contact angle equilibrium

If the angle subtended to the horizontal plane by the surface of the deformed solid is α, then obviously:

$$\frac{\gamma_{LV}}{\sin 2\alpha} = \frac{\gamma_{SL}}{\sin(\theta - \alpha)} = \frac{\gamma_{SV}}{\sin(\theta + \alpha)} \quad (4)$$

and it follows that:

$$\frac{\gamma_{LV}}{\gamma_{SV} + \gamma_{SL}} = \frac{1}{\sqrt{1 + \beta\cos^2\theta}} \quad (5)$$

where:

$$\beta = \frac{4\gamma_{SV}\gamma_{SL}}{(\gamma_{SV} - \gamma_{SL})^2} \quad (6)$$

Writing $y = \frac{\gamma_{LV}}{\gamma_{SV}}$ and using equation (1), it follows that:

$$\cos\theta = (2\varphi - \sqrt{y})\sqrt{\frac{(1 - \varphi\sqrt{y})(1 + y - \varphi\sqrt{y})}{y(1 + y - 2\varphi\sqrt{y})}} \quad (7)$$

This may be compared with:

$$\cos\theta = \frac{2\varphi}{\sqrt{y}} - 1$$

for the case when deformability of the substrate is ignored.

The symmetrical form of the deformation, on which this result depends, is indeterminate from equilibrium of interfacial tensions alone, since any rigid-body rotation imposed on the system of forces cannot affect equations (4) in any way. But, in the absence of absorption, the properties of the solid phase below the interface are invariable and the condition of energy minimization would be thought, therefore, to lead to the symmetrical configuration shown in Fig. 1. This, in any case, is the natural modification of Young's equation, wherein both angles α are zero. Again if β is allowed to become sufficiently large, the limiting form of equation (5) is Young's equation, but in cases of greatest interest with organic substrates β is a number of order unity and equation (2) is then a very inadequate approximation to (5).

It is easily shown that equation (7) deviates hardly perceptibly from a rectilinear form provided φ is not too far from unity.

For the particular value $\varphi = 7/8$ it may be shown that the function given by the expression (7) intersects the straight line to which it approximates at its midpoint. It will be seen that the curve is virtually indistinguishable from this line (Fig. 2). On the other hand, if the deformation of the surface is neglected the corresponding dependence shows considerable curvature. It is generally recognized[5] that Zisman's rectilinear plots refer to solids where $0{\cdot}8 < \varphi < 1{\cdot}0$ so that the rectilinear form follows naturally as a result of surface deformability for such materials.

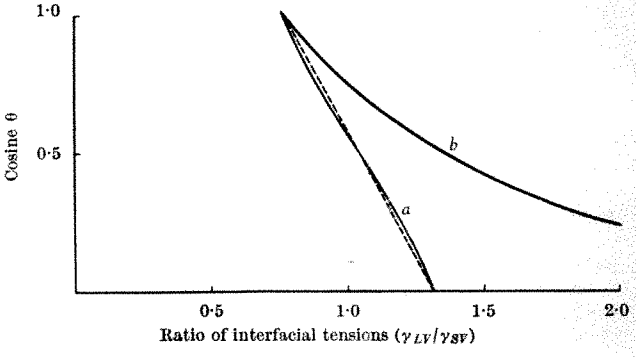

Fig. 2. The relation between cosine θ and the interfacial tension ratio. *a*, Calculated for a deformable substrate; *b*, calculated on the basis of Young's equation

The slope of the Zisman plots is readily related to the interaction parameter. Referring to equation (7), it is seen that $y = \varphi^2$ corresponds to $\cos\theta = 1$ and $y = 1/\varphi^2$ corresponds to $\cos\theta = 0$, so that the slope in question is given by $\varphi^2/1 - \varphi^4$. For forces that are of dispersion type, and φ exactly equal to unity, the Zisman line would be parallel to the vertical axis and contact dependent on the stringent requirement $\gamma_{LV} = \gamma_{SV}$, that is, $y = 1$. In this limiting case the rectilinear property is, of course, attained exactly.

For solid materials, the vector diagram usually known as Neumann's triangle[6] can only properly be applied to interfacial tensions derived from the Helmholtz free energy for the system as a whole. Defined in this way there is included a contribution from the deformational energy of the solid phase which, unfortunately, bears no simple relation to the surface free energy[4]. Since the relation (1) is more naturally applied to specific surface

free energies, it is perhaps inevitable that φ cannot be regarded as strictly constant for interfacial tensions as well.

In some organic solids, notably polytetrafluoroethylene, stress relaxation may be relatively rapid on account of the known facility for molecular chain rotation and translation[7], a tendency which should be enhanced in the surface layers on account of diminished packing density. In such cases the distinction between interfacial tension and intrinsic surface energy will tend to disappear, although some dynamic effects concerning contact angles might well be attributed to the actual rate of stress relaxation in the interfacial zone.

The rectilinear relationship established empirically by Zisman *et al.* would, therefore, seem to be consistent with the view that wetting phenomena depend significantly on surface deformability as well as on intrinsic surface energy effects. Consequently, Young's equation does not describe the boundary conditions as well as Neumann's triangle, in spite of the prevailing view that the latter applies only to liquids. As a corollary, it may be conjectured that the surface layers of organic solids are partially disoriented and exhibit a degree of mobility more characteristic of a liquid or gel. Dynamic effects would, on the same view, depend on the actual magnitude of the relaxation time for molecular re-orientation at the interface[8].

$Ca_8Si_5O_{18}$ and the Nature of "γ-Dicalcium Silicate Hydrate"

Hydrothermal treatment of mixtures of γ-Ca_2SiO_4 and quartz has yielded a new compound of probable composition $Ca_8Si_5O_{18}$, or $8CaO.5SiO_2$. This is formed, together with other products, over a wide range of conditions (bulk $CaO : SiO_2$ molar ratio 1·5–2·0, temperature 180°–600° C, pressure 10–200 bars, time 3–14 days). It has not yet been obtained in a pure form, but a preparation containing it with only small proportions of γ-Ca_2SiO_4 and wollastonite was obtained by treating a mixture of bulk $CaO : SiO_2$ ratio 1·75 for 14 days at 600° C and 200 bars.

The crystals were of micron size and anhedral. Selected-area electron diffraction showed them to be orthorhombic, with *a*, 11·54 Å; *b*, 5·09 Å; *c*, 28·86 Å. Systematic absences were found of *h0l* reflexions with *h* odd, and of *0kl* reflexions with *l* odd; the space group could therefore be *Pcam* or $Pca2_1$. The principal X-ray powder spacings (in Å) were at 3·60 (*ms*), 3·05 (*vs*), 2·84 (*s*), 2·69 (*s*), 1·95 (*ms*), 1·895 (*ms*), and 1·806 (*ms*). The X-ray powder pattern was indexed and indicated cell parameters differing slightly from those obtained by electron diffraction: *a*, 11·45 Å; *b*, 5·09 Å; *c*, 28·70 Å. The *ab*-face of the unit cell is virtually identical in parameters with those of γ-Ca_2SiO_4 (ref. 1) and kilchoanite (a polymorph of $Ca_3Si_2O_7$) (refs. 2 and 3). Comparison of indexed X-ray powder patterns showed that the Fourier transforms of $Ca_8Si_5O_{18}$ and kilchoanite are closely similar. The infra-red absorption spectra of the two compounds are also very much alike.

These facts strongly suggest that the new compound has an interstratified structure formed by the regular alternation in the *c*-direction of layers of γ-Ca_2SiO_4 and kilchoanite. The unit cell of γ-Ca_2SiO_4 has $c = 6·78$ Å and atomic contents $4[Ca_2SiO_4]$ (ref. 1); that of kilchoanite has $c = 21·95$ Å and atomic contents $8[Ca_3Si_2O_7]$ (refs. 2 and 3). The unit cell of the interstratified compound would thus be expected to have $c = 28·73$ Å and atomic contents $4[Ca_8Si_5O_{18}]$. The predicted and observed cell parameters agree closely with each other, and the postulated chemical composition is compatible with the experimental evidence.

An apparent compound of composition $2CaO.SiO_2.0·26–1·00\ H_2O$ has been reported by various investigators as the product of hydrothermal treatment of β- or γ-Ca_2SiO_4 at 160°–300° C under pressures of saturated steam, and is generally known as "γ-dicalcium silicate hydrate" (ref. 4) or "$C_2SH(C)$" (ref. 5). The X-ray powder pattern, infra-red absorption spectrum, and thermal weight-loss curve of this material have been redetermined and are consistent with the view that it is a mixture consisting predominantly of calciochondrodite ($Ca_5(SiO_4)_2(OH)_2$) (ref. 6) and $Ca_8Si_5O_{18}$ or a phase closely resembling it. Electron microscopy and selected-area electron diffraction (ref. 7) show that it also contains kilchoanite.

Absorption Spectra of Methylene Blue in Benzene

Dyes are generally investigated in aqueous media because of their insolubility in benzene and similar solvents. We have found[1] that many dyes, if extracted with benzene at a suitable *p*H, pass into the benzene medium, very often with a change of colour. This communication reports our preliminary results with methylene blue.

In Fig. 1, curves *A* and *B* are the absorption spectra of methylene blue in water and in a buffer of *p*H 11·2, respectively; it is evident that the shoulder of curve *A* at 610 mμ becomes quite prominent in the buffer. The shoulder has been ascribed by Rabinowitch and Epstein[2] to the dimer. The benzene extract of the dye solution in the aforementioned buffer is red in colour; curve *C* shows the absorption spectra in benzene. This red form of methylene blue was reported by Lewis[3] to be formed by the addition of hexane to an alcoholic solution of methylene blue. Lewis considered this to be a new form of dye. We recovered this red form of the dye as a solid (partly soluble) from the benzene extract by freeze-drying technique; the same could be dissolved in water and the absorption spectra are shown by curve *D* in Fig. 1. It would be seen that this red form has the peak exactly at the shoulder of the curves *A* and *B*. We conclude that the red form of methylene blue is not a new form of the dye as supposed by Lewis but is the dimer—its red colour in benzene being due to a solvent effect. The alternative idea that the red form is the carbinol base is discounted by the fact that the aqueous solution of the red form does not become blue on addition of acid. The shift in the position of the peak (curves *C* and *D*) is remarkably large. If the red form is dried strongly and dissolved in dry benzene, the position of the peak shifts somewhat towards longer wave-length, as is shown by the curve *E*. Evidently the effect of moisture on the absorption spectra of the red form of the dye is quite strong.

The absorption spectra of the red form in benzene solution are highly sensitive to acids or polymers containing sulphate and similar end-groups and to comparatively high concentrations of hydroxylic compounds. The peak at 515 mμ in benzene is not only shifted under such conditions to longer wave-lengths but shows a number of subsidiary peaks. Fig. 2 illustrates two such shifted absorption spectra by the addition of about 0·2 mM polymer sulphate (curve *B*) and by the addition of a large quantity of ethyl alcohol (curves *C*–*E*). Curve *A* shows the absorption maxima of the dye in benzene under the same condition. This is similar to the solvent effect observed by Sheppard[4] on merocyanine dye (polymethine dyes). All the optical measurements were recorded from a Hilger 'Uvispek' photoelectric spectrophotometer using 1-cm stoppered silica cells at room temperature (≈ 27° C). Studies of other cationic dyes in benzene and similar solvents using our extraction technique[1] are being made.

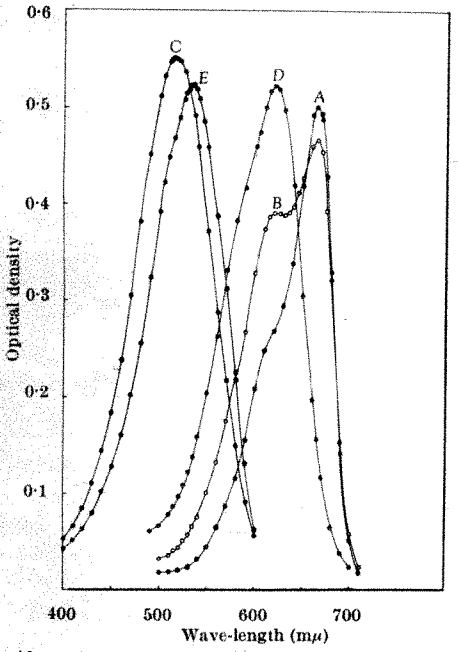

Fig. 1. Absorption spectra of methylene blue in *A*, water; *B*, buffer *p*H 11·2; *C*, benzene (red form); *D*, water (red form); *E*, dry benzene (dried red form)

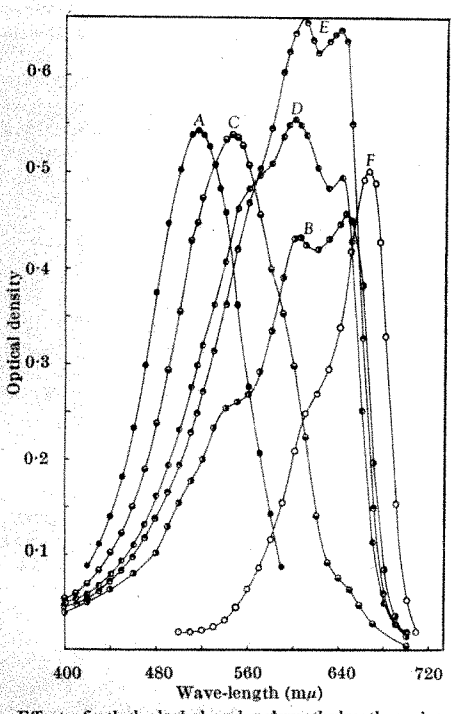

Fig. 2. Effect of ethyl alcohol and polymethylmethacrylate (PMMA) having sulphate end-group on red form of methylene blue in benzene. *A*, in benzene; *B*, on addition of PMMA; *C*, *D*, *E*, on addition of ethyl alcohol 20 per cent, 70 per cent and 90 per cent by volume, respectively; *F*, methylene blue in water

BIOCHEMISTRY

Effect of Bailey's Tropomyosin Purification on EGTA-sensitizing Activity

Ebashi discovered that EGTA or Ca^{++} insensitive, non-relaxing actomyosin could be made EGTA sensitive by a third protein which exhibited physico-chemical properties characteristic of Bailey's tropomyosin B (ref. 1). However, he found no EGTA-sensitizing activity in Bailey's tropomyosin, and his new protein lost its activity when subjected to Bailey's procedures required for purification. Ebashi concluded that his EGTA-sensitizing protein was a new 'tropomyosin-like' protein or a native form of tropomyosin *B*. He offered no explanation concerning the difference between his 'tropomyosin-like' EGTA-sensitizing protein and Bailey's tropomyosin *B*.

In repeating Ebashi's preparation I noticed a striking discrepancy in the effect of the ammonium sulphate precipitation (60 per cent saturation) on the activity of the protein. In his experience[1] this precipitation led to inactivation and therefore had to be omitted from the purification procedure. In my experience this led to an increase in specific activity. Ammonium sulphate essentially free of trace contamination with heavy metal was used in our procedure; the usual commercial preparations are known to contain such trace contamination.

This situation suggested a parallel to that encountered by Kominz *et al.*[2,3] in determining the SH content of tropomyosin *B*. The 'salting-out' steps in the Bailey preparation led to a loss of SH groups due to the presence of heavy metals in commercially available ammonium sulphate. According to Drabikowski[4], even in the absence of heavy metals, the Bailey procedure leads to a variable loss of SH groups.

In order to investigate whether this loss of SH groups is responsible for the lack of EGTA-sensitizing activity we have prepared tropomyosin *B* by the Bailey method[5] with 0·5 mM dithiothreitol[6] present in all preparative solutions. A parallel preparation was carried out in which the protecting reagent for sulphydryl groups was absent. Crude tropomyosin extract and the protein obtained after Bailey's first, second and third purification cycle were assayed for their effect on the contractile response of synthetic actomyosin (Fig. 1).

In the preparation carried out in the presence of the protective reagent for sulphydryl groups (Fig. 1*A*), the EGTA-sensitizing activity of the crude tropomyosin extract increased greatly during the first purification cycle. Further purification cycles caused only a slight increase of the EGTA-sensitizing activity.

In the preparation carried out in the absence of the protecting thiol (Fig. 1*B*), markedly less EGTA-sensitizing activity was present. The activity of the crude extract also increased during the first purification cycle; however, further purification cycles caused a variable decrease of EGTA-sensitizing activity. Dialysis against 0·5 mM

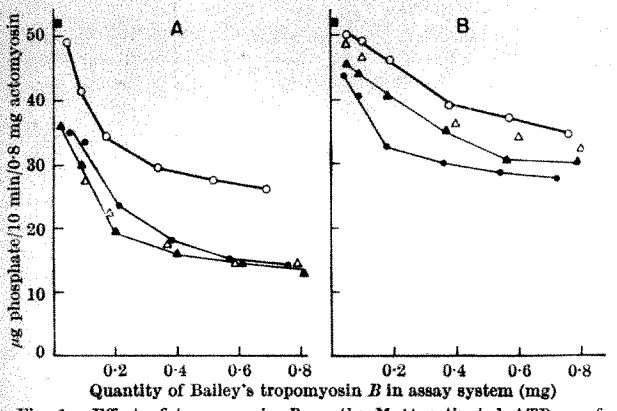

Fig. 1. Effect of tropomyosin *B* on the Mg^{++} activated ATPase of Ca^{++} insensitive synthetic actomyosin. *A*, Preparation carried out in presence of 0·5 mM dithiothreitol. *B*, Same preparation carried out in absence of dithiothreitol. ○, Tropomyosin extract not purified; ●, tropomyosin obtained after one purification cycle; ▲, tropomyosin after two purification cycles; △, tropomyosin after three purification cycles; ■, no tropomyosin present (control experiment). Assay system contained 0·8 mg actomyosin in 2 ml. Reaction medium: 0·06 M potassium chloride, 0·02 M imidazole (*p*H 6·75), 5 mM potassium-oxalate; 5 mM magnesium chloride; 1 mM ATP; 2·0 mM phosphoenol-pyruvate, 0·025 mg/ml. pyruvate kinase; 1 mM EGTA

dithiothreitol increased the EGTA-sensitizing activity to a level similar to that of the protein extracted and purified in the presence of the sulphydryl protecting agent. Dithiothreitol by itself had no effect on the EGTA-sensitivity of synthetic actomyosin.

Comparative assay experiments were carried out on Ebashi's protein (not shown) under identical conditions. The specific activity of the Ebashi preparation[1] corresponded approximately with that of Bailey's tropomyosin obtained after the first purification cycle.

These experiments indicate that EGTA-sensitizing activity requires sulphydryls which are lost during the usual Bailey preparation when these groups are not protected. Spectrophotometric analyses[7] of the sulphydryl content revealed 0·04–0·06 μmoles SH per mg protein for the preparations with high EGTA-sensitizing activity of Fig. 1*A*. Variable lower analytical values were obtained in the corresponding preparations (of Fig. 1*B*) with low EGTA-sensitizing activity.

In apparent conflict with this conclusion are recent findings of EGTA-sensitizing activity in preparations in which the presence of tropomyosin has not been demonstrated[8–11]. Two explanations probably account for these observations: (1) EGTA activating SH-tropomyosin may form complexes with other proteins whereby its characteristics are altered (SH groups in the complexes may be protected); (2) the criteria used for demonstrating tropomyosin were those of *SS*-tropomyosin and not of SH-tropomyosin. A previously implied third explanation[9] that EGTA-sensitization of synthetic actomyosin may not be a specific activity of a specific protein appears unwarranted in the light of the present investigations.

I thank Miss B. Olson and Mr. J. Capets for their assistance in this investigation, which was supported in part by grants from the American Heart Association, 64 *G* 33, and the U.S. Public Health Service, National Institutes of Health *HE* 09544-01.

Ultra-violet Extinction Coefficients of some Muscle Nucleotides and Purines at *p*H 7·0 and in 2 N Hydrochloric Acid

THE nucleotides and purines extracted from muscle were separated on anion-exchange columns and estimated by the methods of Hurlbert *et al.*[1], as modified by Kassemsarn *et al.*[2] and Jones[3]. Fractions of eluate containing the nucleotide or purine peaks were identified by their absorbances at 260 mμ. After bulking the fractions in each peak, the solutions were made 2 N with respect to hydrochloric acid, and quantitatively determined by measuring the extinction of the solutions in the ultra-violet region.

Conflicting values have been given in the literature for the millimolar extinction coefficients of two of the muscle nucleotides—adenosine-5′-diphosphate (ADP) and adenosine-5′-monophosphate (AMP)—and for three of their degradation products—inosine monophosphate (IMP), inosine, and hypoxanthine[4–7]. Thus, for AMP, E_{max} (at 258 mμ) at *p*H 7·0 is given as 14·0 by Bendall and Davey[5] whereas according to Bock *et al.*[4] this value is 15·4 (at 259 mμ). The ultra-violet spectra of these substances were therefore examined.

5′ AMP (monohydrate) and 5′ IMP (disodium heptahydrate), inosine and hypoxanthine (supplied by Koch-Light and Co., Colnbrook), were used in 5×10^{-5} M solution, in both 2 N hydrochloride and at *p*H 7·0 (phosphate buffer).

Measurements of absorbances over the wave-length range 230–280 mμ were made, against the appropriate blanks, in 1 cm silica cells, with a Hilger 'Uvispek' spectrophotometer. The millimolar extinctions obtained are given in Tables 1 and 2.

The extinction values obtained at *p*H 7·0 for 5′ IMP and 5′ AMP agree closely with those given by Bendall and Davey[5]. Values for 5′ AMP are very similar at *p*H 7·0 and in 2 N hydrochloric acid. The same *p*H change, however, exerts a very significant effect on the ultra-violet spectra of 5′ IMP, inosine and hypoxanthine.

The millimolar E_{max} for inosine, at *p*H 7·0 and in 2 N hydrochloric acid, are respectively 12·4 (at 249 mμ) and 11·3 (at 250 mμ). The value for hypoxanthine at *p*H 7·0 is 10·5 (at 249 mμ), and in 2 N hydrochloric acid this becomes 11·0 (at 247 mμ).

5′ IMP may not be completely separated from 5′ ADP on the ion-exchange column. These nucleotides may be quantitatively determined, when present together, by measuring the extinction of the bulked solution at the two wave-lengths, 265 mμ and 275 mμ. Assuming that the extinction values for 5′ ADP are not significantly

Table 1

Wave-length (mμ)	5′ AMP		Wave-length in mμ	5′ IMP	
	*p*H 7·0	In 2 N HCl		*p*H 7·0	In 2 N HCl
230	1·9	3·3	230	4·4	3·1
240	5·2	6·0	240	9·8	7·6
250	11·1	11·5	245	11·8	9·5
255	13·5	13·8	248	12·3	10·2
257	14·1	14·2	250	12·3	10·4
258	14·3	14·2	252	11·6	10·5
259	14·3	14·1	253	—	10·4
260	14·3	14·0	255	9·9	10·1
261	14·2	—	260	7·3	8·6
265	13·0	12·7	265	5·3	6·5
270	9·4	10·0	270	4·1	3·9
275	5·0	6·2	275	2·9	1·8
280	1·9	3·3	280	1·9	0·7

Table 2

Wave-length (mμ)	5′ Inosine		Hypoxanthine	
	*p*H 7·0	In 2 N HCl	*p*H 7·0	In 2 N HCl
230	5·3	4·8	4·2	5·7
240	10·1	8·8	8·2	9·6
245	11·9	10·5	9·9	10·8
247	12·2	—	10·4	11·0
248	12·3	11·2	10·5	11·0
249	12·4	11·3	10·5	10·9
250	12·2	11·3	10·5	10·8
251	12·0	11·3	10·4	10·7
255	9·9	10·8	9·5	9·6
260	7·3	9·3	7·8	7·6
265	5·4	7·0	5·6	5·3
270	4·1	4·6	3·4	2·7
280	1·8	1·1	0·6	0·5

different from those of 5′ AMP at these wave-lengths[4,7], the millimolar concentrations of 5′ IMP and 5′ ADP may be obtained from the equations:

$$E_{265} = 12{\cdot}7\,x + 6{\cdot}5\,y$$
$$E_{275} = 6{\cdot}2\,x + 1{\cdot}8\,y$$

where E_{265} and E_{275} represent the absorbances of the solution (in 2 N hydrochloric acid) at 265 and 275 mμ, and where x and y represent the millimolar fractions of 5′ ADP and 5′ IMP present in the solution.

Enzymatic Determination in Serum of Lathyritic and Prednisone-treated Lathyritic Rats

While a remarkably raised serum-level of transaminases and aldolase is found in dermatomyositis, such augmentation, as a rule, is not found in cases of severe muscular involvement of scleroderma and disseminated lupus erythematosus (acutus)[1–3].

With this in mind, we investigated whether, in an acute experimental collagenose, that is lathyrism, the enzymatic activity in serum of glutamic-oxalacetic-transaminase (GOT), glutamic-pyruvic-transaminase (GPT), aldolase (ALD) and lactic-dehydrogenase (LDH) would be changed by an uptake of β-amino-proprionitrile. Using the procedure of Holzmann *et al.*[4], eighteen albino rats on standard altromin diet were divided into three groups. Group 1 (six animals) received 40 mg β-amino-proprionitrile daily; group 2 (six animals) received 40 mg β-amino-proprionitrile plus 0·5 mg prednisone daily; group 3 (six animals) served as a control. After 17 days the serum enzymatic activity was measured, using the 'Biochemica-test' combinations (Messrs. Boehringer, Mannheim).

As can be seen from Table 1, in serum of lathyritic rats, the activity of the transaminases, but not that of ALD or LDH, is raised in comparison to normals. The findings were more significant in the case of GPT than in that of GOT, whereas in the prednisone-treated lathyritic animals the transaminase-levels were again within the normal range. The single and probably non-specific intensification of the transaminases which was detected is probably due to primary lathyrogenic effects of β-amino-proprionitrile on the mesenchyme and may result from generally increased permeability of cells[5,6]. Moreover, an elective augmentation of these enzymes by raised suppliance of substrate[5] as a consequence of enhanced collagen destruction[4,7] can also be assumed. Furthermore, such mechanisms are in agreement with the control of elevated transaminase-values by corticosteroids[8,9].

The finding of heightened activity of transaminases in lathyritic rats confirms the clinical belief that these enzymatic activities are mainly related to acute disintegration of collagen, for example, in dermatomyositis, and are far less closely related to chronic collagen diseases such as scleroderma.

Table 1. Enzyme-levels in Rats

	Group 1	Group 2	Group 3
LDH

High Nucleo-cytoplasmic Concentration Gradient of Chloride in Rat Liver

Previously, a high nucleo-cytoplasmic concentration gradient of sodium was found in rat liver and other tissues[1,2]. Since the concentration of potassium also was higher in the nucleus than in the cytoplasm, about 500 μequiv./g dry weight of anions should exist in the nucleus if the assumption is correct that nucleic acids and basic proteins approximately neutralize each other. This communication presents data which demonstrate a high concentration of chloride in the nucleus of the rat-liver cell.

Nuclei were prepared by the non-aqueous technique[3]. Analyses for chloride were performed, after digestion with 0·1 N nitric acid, by mercurimetric titration[4] in a recording Zeiss spectrophotometer; the end-point was evaluated by graphical means. By this method 104 per cent of the chloride which was added to the tissue fractions was 'recovered'. None of the materials and solvents which were used for the isolation of nuclei raised the blank values above the limit of error. Tissue preparations which were freed from lipids by exposure to the solvents of the non-aqueous procedure did not lose or gain any chloride.

The results (Table 1) demonstrate a concentration gradient of chloride of about 10 between cytoplasm and nucleus. This gradient compares well with that of intra-

Table 1. Concentration of Chloride in Rat-liver Whole Tissue and Nuclei

Tissue fraction	Experimental conditions	RNA/DNA	Cl^- (μeq./g) Dry weight	Cl^- (μeq./g) Fresh weight	No. of analyses
Whole tissue*	1	2·9	135	41	14
Cytoplasm†	1	—	35	10	—
Nuclei*	1	0·21	204	95	18
Whole tissue	2	2·0	42	—	2
Nuclei	2	0·50	68	—	2
Whole tissue	3	2·7	270	—	2
Nuclei	3	0·41	347	—	2

Experimental conditions: (1) analysed as obtained; (2) after perfusion of the livers of 40 animals *in vivo* with 0·30 M sucrose; (3) after perfusion of the livers of 40 animals *in vivo* with 0·15 M lithium chloride.
* These data represent the average of ten different batches of tissue preparations obtained from 40–50 animals each.
† Derived data from analyses of whole tissue and nuclei, after corrections for the chloride content of blood (10 per cent of fresh weight), of extracellular fluid (15 per cent of fresh weight), and of nuclei (6·6 per cent of fresh weight)[2].

cellular sodium[2]. Most of the nuclear chloride was removed by liver perfusion *in vivo* with a salt-free solution (experiment 2) and the concentration was considerably raised by perfusion *in vivo* with a chloride solution (experiment 3). Furthermore, after *in vitro* incubation of nuclei for 30 min (50 mg dry weight in 5 ml. 0·075 M SO_4^{2-}, containing Na^+ and/or K^+ in different proportions), more than 90 per cent of the chloride originally contained in the nuclei was recovered in the incubation medium.

Existing data[2] suggest that there are about 160 μequiv. Na^+/g dry weight and 320 μequiv. K^+/g dry weight in rat-liver nuclei, as compared with about 200 μequiv. Cl^-/g dry weight (Table 1). Therefore, about 40 per cent of nuclear alkali cations are neutralized by chloride. The deficit of anions which still remains is not covered by sulphate; analyses of the aforementioned liver fractions for total sulphur by the method of Tölg[5] revealed 24 μequiv./g dry weight in whole tissue and 4 μequiv./g dry weight in nuclei. Sulphate would only account for a fraction of the total sulphur content.

Nuclear chloride may be a component of the sodium space of the nucleus[6], the function of which, however, is not as yet fully understood. Anyway, a distinct cellular site of high chloride concentration exists which is very similar to the concentration of chloride in the extracellular fluid. Information concerning the size and the significance of the chloride space in tissues and also the chloride potentials can be deduced from the data given in Table 1, which goes to show that cellular chloride is not distributed uniformly.

Calf Thymus and Chicken Erythrocytes Nucleoproteins

We have prepared a large series of nucleoproteins (DNP) from calf thymus by the method of Zubay and Doty[1] and, unlike these authors, have obtained amounts of gel (gDNP) that varied from 0 to 80 per cent. We were thus surprised to find that extraction of DNP from chicken erythrocytes by the same procedure regularly gave high percentages of gel; of six preparations, five gave 90 per cent or more gDNP.

The most important difference between the two series of preparations, aside from the origin of the starting materials, was the way in which they were obtained. The chicken blood was collected directly in the sodium chloride-versene used for washing the nuclei, but thymus could not be processed immediately; it was frozen at variable times after the death of the animal, and frequently processed after more or less prolonged sto in a refrigerator. Furthermore, the percentage of DN gel was higher when enzymatic activity was stopped rapidly, as shown by the results with erythrocytes. This observation suggested that the soluble DNP (sDNP) might represent degraded material. To determine the nature of this degradation we prepared a new series of calf thymus nucleoproteins reducing the time before the tissue was frozen, in order to approach the conditions used in collecting the erythrocytes. We also kept the thymu for varying periods of time before starting the preparation, and noted the amounts of gDNP and sDNP obtained. We then undertook an analysis of the two types of DNP. Great care was taken to avoid mechanical degradation when the DNA was being extracted; its molecular weight was determined by light scattering in M sodium chloride.

Preparations made from thymus frozen 10–15 min after the animal had died produced between 92 and 98 per cent of gDNP. The DNA extracted from these DNP preparations had a molecular weight of 10·5–15·5 million.

Of three other preparations made from the same thymus, one, *V*123, had been homogenized 15 h earlier in 0·15 M sodium chloride and left at 0° C. All gave high percentages of gel, 97, 96 and 92 per cent; but the molecular weight of the DNA from gel *V*123 was only 6·5 million, whereas the other two gave values of 10·9 million.

Three preparations made from three different lots of thymus yielded variable amounts of sDNP and gDNP. Thymus *V*127, left 15 h at 23° C before processing, gave 42·4 per cent gel and 57·6 per cent soluble DNP, the molecular weight of the DNA extracted from DNP 127 gel was 8·2 million while that of *V*127 soluble DNA was 5·1 million. Thymus *V*128, stored in a freezer for 3 weeks, gave 77·6 per cent gel, and *V*266, frozen for 2 months, gave 76·3 per cent. The molecular weights of the gel DNAs were, respectively, 6·7 and 7 million; those of the DNAs from the two sDNP only 2·8 and 2·4 million. (The DNAs extracted from two lots of poorly washed[2] erythrocyte nuclei, which had been allowed to stand for 24 h at 0° C, also had very low molecular weights, 0·9 and 1 million.) Thus, in the sDNP that we have examined the molecular weight of the DNA has always been lower than that of the DNA from the corresponding gel, so that the sDNP must have undergone some nuclease action.

Chemical analysis of the sDNP and gDNP from thymus gave mean nitrogen : phosphorus ratios of 4·15 for the gels and 3·80 for the soluble fractions; a gDNP seems to be richer in protein than the corresponding sDNP. The lability of the sDNP was shown by its precipitation in 0·15 M sodium chloride; soluble DNP left 2–2·5 times as many small and dialysable protein fragments in solution. This suggests that the protein of the sDNP has also been attacked enzymatically[3,4] and that the resulting fragments are easily detached. In a DNP gel the protein fraction responsible for the constitution of a network between DNA molecules probably remains intact.

It should be emphasized that we have found no difference in the nitrogen : phosphorus ratio of the s and g fractions of chicken erythrocyte DNP and that this ratio is lower than that of the thymus gels. This suggests that the gDNP of thymus may be richer in some particular histone, perhaps active in gene regulation, that is responsible for the state of the gel, is more labile than other histone fractions, and is removed from sDNP. We are continuing these investigations in order to verify this hypothesis.

croscopic Localization of Amines entral Nervous Tissue

have been detected in the central eans of a fluoresc chnique[1], and made regard tent of the prese nerv

Several techniques for fine-structural norepinephrine localization have been reported in adrenomedullary tissue[4–7]. One of these[4,5] has been used to detect amines in the central nervous system. This communication reports some results obtained with a group of Syrian hamsters.

Adult Syrian hamsters were perfused, by way of the ascending aorti, with cold (4° C) 4 per cent glutaraldehyde in 0·1 M sodium cacodylate buffer (*p*H 7·21) for 40–60 min at a pressure of 100–120 mm mercury. The brains were removed following perfusion, hypothalami dissected out, tissue diced and placed in fresh cold fixative for 1 h. Cubes of brain material were rinsed overnight in cold (4° C) sodium cacodylate buffer (*p*H 7·21) which contained 4 per cent sucrose. Cubes were then incubated for 24 h at 4° C in a solution of 2·5 per cent potassium dichromate and 1 per cent sodium sulphate in a 0·2 M acetate buffer (*p*H 4·1) (ref. 8). Half the incubated blocks were later treated with 1 per cent osmium tetroxide[9] for 90 min. All tissues were dehydrated in graded alcohols and embedded in 'Epon'. Sections were prepared using an LKB 'Ultratome' and examined on an RCA '*EMU-3F*' electron microscope.

Fig. 1 illustrates hypothalamic material which was incubated in dichromate following glutaraldehyde fixation. This procedure shows only the reaction sites of the amines. Granules of this nature were seen throughout the tissue. Figs. 2 and 3 show tissues which, in order to provide identification of surrounding structures, have been treated with osmium tetroxide following dichromate incubation. Fig. 2 demonstrates granules of varying density within vesicles together with smaller vesicles which appear to be empty. The empty vesicles may represent the site of storage of another type of transmitter or they may be vesicles which at one time or another contained granules. Fig. 3 shows electron-dense granules which are different from those in Fig. 2. The granules in Fig. 3 may be in the process of storing or releasing amine, but it is possible that the different appearance might be due to osmotic changes induced during the process of preparing the tissue.

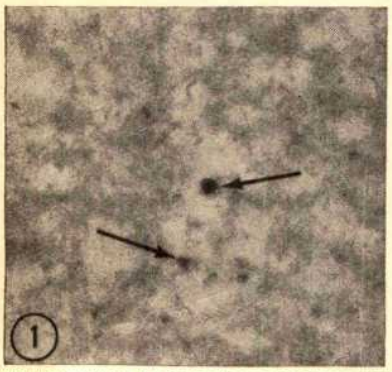

Fig. 1. Hamster hypothalamic tissue: 4 per cent glutaraldehyde fixation with potassium dichromate incubation. Arrows point to granular sites of amine localization. (× 30,000)

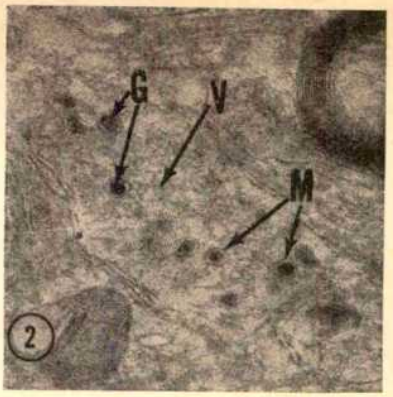

Fig. 2. Hamster hypothalamic tissue: prepared as in Fig. 1 but also treated with osmium tetroxide. Amine granules (*G*) of varying densities surrounded by membranes (*M*) are present in the nerve terminal. Vesicles (*V*) which appear to be empty are also present. (× 30,000)

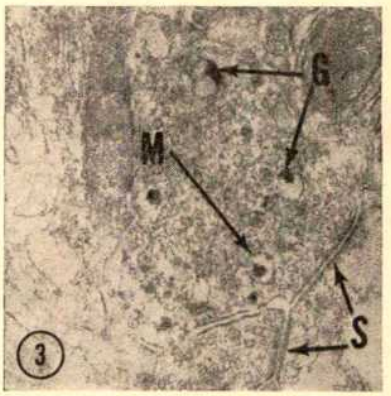

Fig. 3. Hamster hypothalamic tissue prepared as in Fig. 2. Some granules (*G*) have assumed an eccentric location within the granule membrane (*M*). Synapses (*S*) are also evident at this terminal. (× 30,000)

Although the reaction is known to localize norepinephrine at the fine-structural level, it is possible that other biologically occurring amines which possess unsubstituted amino groups may also be demonstrated. *In vitro* investigations were performed and revealed that both dopamine and 5-hydroxytryptamine (5HT), both with unsubstituted amino groups, can also be demonstrated by means of this technique. *In vitro* experiments were conducted using amine concentrations ranging from 6×10^{-3} M to 6×10^{-4} M. Amines tested were epinephrine, norepinephrine, dopamine, 5HT, dihydroxyphenylalanine (DOPA), phenylalanine and tyrosine.

Table 1

a. Various amine solutions treated with 4 per cent glutaraldehyde (*p*H 7·2) followed by addition of potassium dichromate (*p*H 4·1) solution

	Amines						
	Norepinephrine	Dopamine	5HT	Epinephrine	DOPA	Phenylalanine	Tyrosine
Glutaraldehyde	(+)	(+)	(+)	(−)	(−)	(−)	(−)
Glutaraldehyde + dichromate	(++)	(++)		(−)	(−)	(−)	(−)

b. Norepinephrine (6×10^{-3} M) treated with [illegible] glutaraldehyde and potassium dichromate (*p*H 4·1) solution

	araldehyde concentration			
0·4–0·01 M	8	5×10^{-3} M	3×10^{-3} M	2×10^{-3} M	1×10^{-3} M
(+)		(+) *	(−)	(−)	(−)
(++)		(++)* 5/6	(−) 1/2	(−) 1/3	(−) 1/6

[illegible]ipitate.
[illegible]nes norepinephrine in test-tube.

Glutaraldehyde concentrations ranged from 0·4 M to 1×10^{-3} M. Reactions were carried out at 4° C, 25° C and 37° C. Aliquots (3 ml.) of the various amine and glutaraldehyde concentrations were mixed and allowed to stand for 2 h, then 3 ml. of the dichromate solution was added and the test-tubes left to stand for an additional 24 h.

Table 1 summarizes the results of these *in vitro* investigations: *a* illustrates the results of treatment of various amines with 4 per cent glutaraldehyde; only those amines with an unsubstituted amino group reacted with glutaraldehyde and later produced insoluble precipitates with the dichromate solution; *b* shows the results of treatment of 6×10^{-3} norepinephrine with various concentrations of glutaraldehyde. It is evident that, when the glutaraldehyde/norepinephrine (G/N) ratio of molecules approaches 1/2, or less, the limit of the reaction is reached. Reaction occurs with excess glutaraldehyde, but when there is excess norepinephrine, no precipitates are formed. This was evident from *in vitro* pilot experiments when it was found that 6·25 per cent glutaraldehyde was less effective than 4 per cent in producing precipitates. It should also be pointed out that reaction rates increased when the temperature was increased.

Tramezzani *et al.*[7] recently postulated that a Schiff monobase is formed by the condensation of glutaraldehyde with the unsubstituted amino group of norepinephrine and that the condensation product reduces ammoniacal silver, thus providing a means of detecting norepinephrine using a light or electron microscope. In the present investigation, formation of the Schiff base was evident and the precipitate was the result of reduction of the dichromate solution to chromium dioxide, which is a brownish-black precipitate recovered from the bottom of the test-tubes. One question which existed regarding the initial reaction was that because glutaraldehyde is a dialdehyde it may possibly react with two molecules of norepinephrine and thus there would exist a disubstituted aldehyde rather than a Schiff monobase with reducing properties. The graded concentrations of glutaraldehyde helped in resolving this question, as it was found that one molecule of glutaraldehyde will react with two molecules of norepinephrine only if there are not sufficient glutaraldehyde molecules present in solution. When there is an excess of amine molecules, both aldehyde groups of glutaraldehyde become complexed, no Schiff monobase is formed and the solution loses its reducing properties. Thus, the reaction proceeds only when there is an excess of glutaraldehyde.

Earlier work using the light microscope in differentiating epinephrine and norepinephrine cells in adrenomedullary tissue[8] revealed that dichromate was essential for the reaction. If the tissue was first placed in formaldehyde, the dichromate reaction was inhibited. In the present investigation, amine solutions were treated with both 10 per cent and buffered 4 per cent (*p*H 7·2) formaldehyde until the amine solution became pink. It was assumed at this point that the reaction in which the isoquinoline derivative of Falck[10] was formed had occurred. Treatment of these solutions with glutaraldehyde produced no evidence of Schiff base formation and no precipitates were formed when dichromate solution was added. The addition of dichromate preceding glutaraldehyde also prevented formation of a precipitate, although the solutions became quite dark in colour.

It is evident from these experiments that the unsubstituted amino group of the compounds tested is important in the completion of the reactions and the production of the insoluble, electron-dense precipitates. It should be pointed out th[illegible] the present tech[illegible] nique can demo[illegible] norepinephri[illegible] from th[illegible]

manner similar to that of the *in vitro* investigations, then the amino groups are free in tissue to react and, therefore, not involved in the natural binding process.

Electrophoresis of the Soluble Proteins of Wheat Leaf

THERE have been several reports of gel electrophoretic separations of leaf proteins. Four components were reported for cabbage leaf[1], seven bands for rice leaf[2], and about six bands for bean leaf[3]. Bean leaf proteins have also been studied by Racusen and Calvanico[4] using preparative gel electrophoresis. Steward and Barber[5] obtained good electrophoretic fractionation of the soluble proteins of *Neurospora crassa*, but observed that extracts from tissues of higher plants yielded bands which were less discrete against a diffuse background. The present paper describes the electrophoresis of the soluble proteins of wheat leaf on 7·5 per cent polyacrylamide gel using a discontinuous *tris* chloride–*tris* glycinate buffer system. The method used gave a well-defined pattern and separated more components than reported previously for leaf tissues.

First and second leaves of 30-day-old wheat plants were ground at 4° C with two parts by weight of sand (acid washed) and one part of 0·05 M phosphate buffer (*p*H 7·5) containing 12·5 per cent glucose. The extract, freed of sand and fibre by centrifugal filtration, was centrifuged at 144,000*g* for 30 min. The clear amber supernatant (containing approximately 8 mg protein/ml.) was used for electrophoresis without further treatment.

Disc electrophoresis was carried out as described by Ornstein and Davis[6] except that the sample (300 μg protein) was applied to the top of the polyacrylamide column by layering under the electrode buffer. Electrophoresis was carried out at room temperature (about 25° C) at 3 m.amp per column for 1 h. Gels were stained with amido black 10*B*[6], and destained electrophoretically at 10 m.amp per column for 1 h. Fig. 1 shows the pattern obtained for *Triticum dicoccum* leaf proteins. The accompanying scan was performed on a 'Photovolt' densitometer (Model 530) equipped with a narrow slit (0·1 mm) and set on response 12.

The use of [illegible]henol blue to mark the chloride–glycine bou[illegible] unnecessary with the leaf extract [illegible]d by a sharp amber band. Staining [illegible] was also associated with the [illegible]ed by comparing its mobility [illegible] particular band (comparative [illegible]r over half of the applied [illegible]nds to Fraction I, reported [illegible]though Fraction I was re-

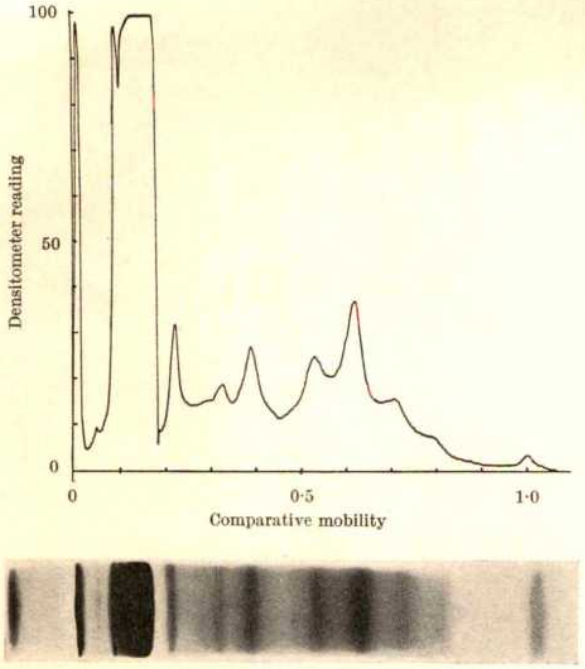

Fig. 1. Electrophoretic separation and corresponding densitometer tracing of the soluble leaf proteins of *Triticum dicoccum*. Direction of migration is left to right. The large pore spacer gel protrudes to the left of the origin

ported[7] to have a higher mobility than the other leaf proteins, its relatively large size (molecular weight of 375,000 (ref. 8)) was probably responsible for its low mobility in 7·5 per cent polyacrylamide (pore size 50 Å (ref. 6)).

At present fifteen to eighteen bands can be distinguished and this may be improved by current investigations designed to refine the technique. The method is being used to investigate the role of leaf proteins in rust infection of wheat plants.

Available Lysine Content of Dried Milk

The heat treatment to which milk is subjected during drying causes some combination between the ε-amino groups of lysine and lactose, which renders such lysine unavailable for nutritional purposes. Since drying conditions on rollers are more severe than [illegible] a spray chamber it is possible that there is less available [illegible] in roller-dried than in spray-dried powder. A ser[illegible]lable lysine determinations was made on both [illegible] number of factories to discover [illegible] this essential amino-acid and to [illegible] are sufficient to cause any def[illegible] ditions of feeding.

Four different batches of [illegible] tories were tested in duplica[illegible] fluorobenzene method as modified by Rao *et al.*[2], and correcting for the loss due to the acid hydrolysis in the presence of lactose. The results are shown in Table 1, together with figures for raw bulk milk. By comparing the results for liquid and dried milk an estimate can be made of the average percentage of lysine destroyed during production in each case.

Table 1. Available Lysine Content of Liquid and Dried Milk

Factory	Available lysine (g/16 g N) Maximum	Minimum	Mean	Average percentage destruction of lysine
		Liquid milk		
—	7·5	7·4	7·4	—
		Spray-dried milk		
A	7·3	6·9	7·1	4·1
B	7·6	7·4	7·4	Nil
C	7·3	6·9	7·1	4·1
		Roller-dried milk		
A	6·5	5·8	6·2	16·2
D	7·3	7·1	7·2	2·7
E	7·4	6·9	7·2	2·7
F	6·5	6·0	6·2	16·2
G	7·3	6·2	6·7	9·5

Table 2. Comparison of the Available Lysine of Human Milk and of Reconstituted Full-cream Roller-dried Powders

	Available lysine (g/16 g N)	Protein (per cent)	Available lysine (mg/100 ml.)
Human milk (ref. 3)	6·2	1·5	93
Reconstituted full-cream roller powder, best individual sample	7·4	3·3	244
Reconstituted full-cream roller powder, worst individual sample	5·8	3·3	191

Table 3. Daily Requirement of the Infant for Lysine

Minimum weight of lysine required per kg body-weight per day (ref. 4)	103 mg
Weight of lysine supplied per kg body-weight per day by full-cream roller powder (70 g):	
(*a*) Best individual sample	347 mg
(*b*) Worst individual sample	274 mg

The loss of lysine in the spray powders, and in the roller powders from factories *D* and *E*, is very small. The loss is greater in roller powders from factories *A*, *F* and *G*, but is in no case sufficiently high to make these products deficient in this amino-acid when used for infant feeding. This aspect is demonstrated in Tables 2 and 3, where comparisons are made with human milk and with the daily requirements of the infant.

All the individual samples of powder examined are richer sources of lysine than is average human milk, and when fed in the proportions normally recommended for infants they will provide two and a half to three times the minimum daily requirements.

Production of Peptide Alkaloids in Submerged Culture by a Strain of *Claviceps purpurea* (Fr.) Tul.

The production of lysergic acid α-ethoxy amide in submerged culture by a strain of *Claviceps paspali* Stev. et Hall was reported earlier[1–3]. The present communication describes the production of ergotamine in submerged culture by a strain of *Cl[illegible] purpurea* (Fr.) Tul. isolated [illegible] sclerotium [illegible] on a variety of Triticale [illegible] This strain [illegible] of Bio-[illegible]

The results (Table 2) show that the *in vivo* treatment of the host prolongs the survival of the skin homograft only if 'Urethan' is used at very high doses. The action of 'Urethan' in the experimental conditions reported here may be partly due to an antigenic simplification induced *in vivo* at the level of the grafted tissue.

It may be concluded that our experiments suggest the possibility of attenuation of the reaction to homograft by means of a chemical antigenic deletion.

Immuno-adsorbents of High Capacity

Preparation of antibodies is greatly facilitated by the use of insoluble immuno-adsorbents. We have found that cross-linkage of soluble antigens with formaldehyde readily yields adsorbents having a high antibody capacity and which are insoluble over a wide range of *p*H. Most experiments have been carried out with an antigen (BSA–CPE) prepared by coupling the diazotized *p*-amino-phenylether of choline (CPE; $NH_2C_6H_4OCH_2CH_2\overset{+}{N}(CH_3)_3$) to bovine serum albumin (10 mols/mole). An insoluble polymer of the BSA–CPE was prepared by slowly adding an equal volume of formaldehyde solution (40 per cent; *p*H 3·1) to a stirred 20 per cent solution of the antigen in 0·15 M sodium chloride. The reaction was allowed to proceed for 1 h at 25° C before the insoluble floccules of antigen polymer were separated by centrifuging. The floccules were washed exhaustively to remove excess formaldehyde with a solution containing 2 M sodium chloride and 0·01 M ammonium chloride adjusted to *p*H 9·0 with ammonium hydroxide, and finally with 0·15 M sodium chloride.

Antibody was extracted from rabbit antisera (1·5 mg antibody/ml.) to BSA–CPE by stirring 250 ml. serum (*p*H 7·0) with 1 g of the polymerized antigen for 30 min at 20° C. The polymer was removed by centrifugation and washed with 0·15 M sodium chloride (*p*H 7·0) until the washings contained less than 10 μg/ml. protein. Washing was then continued with 2 M sodium chloride. The antibody was dissociated from the insoluble antigen by the competitive hapten choline (2 M; *p*H 7) by stirring with successive portions for 15 min at 25° C. Choline was removed by passing through 'Sephadex *G*-75' equilibrated with 0·015 M ammonium acetate. The choline-free antibody solutions were lyophilized and dissolved in a small volume of 0·15 M sodium chloride at *p*H 7·0. The small amount of insoluble protein was removed by centrifugation. The successive elutions by 25, 50 and 50 ml. of choline chloride contained 103, 47 and 15 mg of protein respectively. The total yield of 165 mg represented 71 per cent of the antibody extracted by the antigen polymer and an overall yield of 47 per cent for the single extraction. The purified antibody was 84 per cent precipitable by soluble BSA–CPE. Prolonging the time of contact between antiserum and the polymer increased the overall yield to 80 per cent. The capacity of the antigen polymer was about 300 mg antibody/g. This capacity was somewhat lower than that of the cross-linked protein polymers prepared by Pressman *et al.*[1].

This method has also been used successfully with other determinants, and polymerized BSA has been used to remove anti-BSA antibodies from sera. Dissociation in acid may be substituted for hapten competition.

The method described here would seem to offer a simple and general method for preparing highly purified antibodies against protein-linked determinants and may have a limited application in isolating antibodies to native proteins.

Stimulation of Phagocytosis in Relation to the Mechanism of Action of Adjuvants

Antigens in emulsions of water-in-oil are known to enhance antibody response more effectively than when dissolved or suspended in saline[1], but the mechanism of action of the adjuvant remains unsettled. Freund[2] postulated that absorption, destruction and elimination of antigen are retarded by emulsions of water-in-oil with or without the presence of mycobacteria. Recently, however, Dresser[3,4] found that subcutaneous injection of Freund's adjuvant without antigen enhanced the antibody response against bovine γ-globulin given to mice intravenously: this suggests that the adjuvant exerts a non-specific influence on the immune mechanism. Further, it has been demonstrated that Freund's adjuvant activates the immune machinery in the early phase of the primary immune response preceding the specific response against an antigen[5]. It has also been shown that phagocytosis of the antigen is a crucial step in the induction of the primary immune response[6,7].

Recently we have found that oestrogens have an adjuvant effect on the primary immune response in mice[8]; and previously we have shown that stimulation of the reticulo-endothelial system by the administration of oestrogen raises general body defence as indicated by increased phagocytic activity, raised serum γ-globulin, and increased protection of experimental animals against virulent infections[9]. The present investigation has been designed to ascertain whether stimulation of the phagocytic activity of the reticulo-endothelial system is part of the mechanism of action of Freund's adjuvant.

Intact male white mice (*T.O.* Swiss strain) of 20–25 g body-weight were used throughout. Groups of five animals were used to assess the effect on the reticulo-endothelial system of each dose of adjuvant. Each animal received a subcutaneous or intraperitoneal injection (Table 1) of Freund's incomplete or complete adjuvant (Difco Laboratories) once daily for 3 days in the doses shown. Phagocytic activity was assessed in these animals on the fourth day after treatment had started by measuring the rate of clearance of a known amount of a specially prepared carbon suspension from the circulating blood[10]. For each dose-response experiment five animals were used as controls; they received no treatment and were assessed by the carbon method on the same day as the treated animals. To investigate the speed of action and duration of effect of Freund's adjuvant on the reticulo-endothelial system (Table 2), groups of five animals received a single intraperitoneal injection of 0·2 ml. adjuvant; and on each successive day thereafter, up to the fourth day, phagocytic activity was assessed by the carbon method. Five untreated animals were used daily as controls.

The results are shown in Tables 1 and 2. The index of total-body phagocytic activity is denoted in the tables by the symbol *K*. The *K* value indicates the rate of removal

pressed (post hypoxia) dogs after exchange transfusion with 'anaemic plasma' from previously bled donor dogs, in an attempt to assess these hypotheses.

In order to obtain high concentrations of erythropoietin in donor dog plasma, normal mongrel dogs were bled once daily for 4 days until the haematocrit was 7–11 per cent. Blood volume was maintained by replacing blood drawn with an equal volume of 6 per cent dextran in saline. The erythropoietic marrow of three dogs was stimulated by exposure to a simulated altitude of 18,000 ft. for 10 days. The rate of removal of intravenously injected erythropoietin was determined without removing the dogs from the hypoxic environment. Erythropoiesis was suppressed in dogs by first making them polycythaemic by exposure to hypoxia in a decompression chamber and then returning to sea-level. Three dogs were kept continuously at a simulated altitude of 14,000–21,000 ft. for 90 days (14,000 ft. for the first 2 weeks, increased to 21,000 ft. for the remainder of the exposure). To ensure adequate iron for haemoglobin synthesis, 100 mg of 'Inferon' was given to the dogs before they were exposed to hypoxia. The dogs were then 'returned' to sea-level conditions and the study was commenced on the sixth day after hypoxia. At this point erythropoiesis had become almost completely suppressed, as was judged by the near absence of reticulocytes in the peripheral blood.

The rate of removal of erythropoietin from the plasma of normal dogs, erythropoietically stimulated and erythropoietically depressed, was determined by following the rate of loss after partial replacement of the dogs' plasma with plasma from severely anaemic (bled) donors.

The erythropoietic activity of samples was measured by assay of iron-59 incorporated in the red blood cells, using hypertransfused polycythaemic mice, as described by DeGowin *et al.*[4].

When the curve of plasma erythropoietin disappearance was derived on semilog paper by plotting the amount of erythropoietin remaining in plasma (log scale) against time after exchange transfusion (linear scale), only one component was apparent, which was practically linear to the point where it could no longer be detected (15–24 h). Table 1 shows the average erythropoietin plasma clearance ($t_{\frac{1}{2}}$) of the three groups of animals studied. In the three groups the average half time of disappearance was almost identical. These results agree with those from Naets and Wittek[5], who were unable to detect any effect of erythroid hyperplasia on utilization of erythropoietin, and suggest that there is no correlation between the erythroid activity of the bone marrow and the rate of loss of the hormone from the plasma compartment.

IMMUNOLOGY

Chemical Deletion of Histocompatibility Antigens—Homograft Survival of Rat Skin treated with 'Urethan' *in vitro*

THE prolongation of the survival of homografts has been achieved by treating the recipient host with large doses of drugs which interfere with the immune response[1]. Effective agents are, however, often toxic, so that their use in man is limited.

In recent years evidence has been accumulated in our laboratory that tumour cells treated with various chemical agents *in vitro* lose membrane antigens[2,3]. 'Urethan' has proved to be one of the most effective and least toxic of the compounds so far tested[4].

Because an 'antigenic deletion' at the level of histocompatibility antigens could prevent the early immunological response against a grafted organ, experiments have been carried out to obtain a prolongation of skin homograft survival by pretreating the tissue with chemical agents *in vitro*. Preliminary results have shown that the first-set rejection of skin homografts in the rat can be attenuated if the skin is treated with 'Urethan' *in vitro* before grafting onto the recipient host[5]. This communication reports additional experiments carried out to confirm our previous results.

Adult, randomly bred 2-month-old rats of Sprague-Dawley and Long-Evans strains, weighing about 200 g, were used.

In the first set of experiments, skin from the same donor animal was divided into two strips of equal size (3 × 4 cm). One of them was incubated with 2 per cent 'Urethan' in isotonic phosphate buffer (IPB). The other, the control, was incubated with IPB without 'Urethan'. Both incubations were carried out for 24 h at 37° C. The skin was then grafted onto an animal of the same strain chosen at random, using the technique previously described[6].

The results (Table 1) show that treatment with 'Urethan' is effective in prolonging the survival of the skin homograft. Autotransplants of 'Urethan'-treated skin take very easily and live practically indefinitely, which shows that the treatment does not damage the tissue.

In a second set of experiments, a 'classic' treatment of the recipient host with 'Urethan' was carried out. Cole and Davis[7] observed that 'Urethan', as well as radiation, was able to prolong the survival of skin homografts. We therefore decided to compare the activity of graded doses of 'Urethan' with the results obtained with the pretreatment of the skin *in vitro*.

Fifty rats of Sprague–Dawley strain were divided into five groups of ten animals each. After grafting, recipients were given either 'Urethan' (in doses of 150, 300, 450 and 600 mg/kg respectively) or saline (controls). Two-thirds of the dose was given in the evening and one-third in the morning so as to avoid food intake deficiencies induced by the sedative effect of 'Urethan'.

Table 1. EFFECT OF PRETREATMENT WITH 'URETHAN' *in vitro* ON SURVIVAL OF HOMOGRAFTS

Strain	No. of animals	Treatment	Mean survival time (± *S.E.*) (days)
Sprague-Dawley	12	– (Control)	6·08 ± 0·37
Sprague-Dawley	12	'Urethan' 20 mg/ml	11·8 ± 0·48
Long-Evans	10	– (Control)	6 2 ± 0·29
Long-Evans	14	'Urethan' 20 mg/ml.	10·38 ± 0·51

Vitality of the 'takes' was controlled by injecting the host *in vivo* with disulphyne blue and observing the uptake of the dye and discoloration of the graft

Table 2. EFFECT OF 'URETHAN' INJECTED IN THE HOST ON SURVIVAL OF SKIN HOMOGRAFTS

Strain	No of animals	Treatment	Mean survival time (± *S.E*) (days)
Sprague-Dawley	10	– (Control)	6·1 ± 0·47
Sprague-Dawley	10	'Urethan' 150 mg/kg	6 6 ± 0 38
Sprague-Dawley	10	'Urethan' 300 mg/kg	8 6 ± 0·29

ear) over a period of 2 weeks. The doses were increased from 0·25 ml. to 2·00 ml. of venom solution. The injected rabbits were able to survive amounts at least as great as five times the lethal dose of venom solution. Precipitin assays in test-tubes and on agar plates were positive for the whole venom as well as for the proteolytic and unidentified electrophoretic fractions.

The venom did not show any activity for coagulant or anticoagulant factor, histamine, histamine-liberating substances or any ileum contracting agent, acetylcholine, acetylcholinesterase, acetylcholinesterase inhibitor, phospholipase *A*, ATP phosphohydrolase, ribonuclease, NAD nucleosidase, D- and L-amino-acid oxidase.

We thank Dr. L. Dávila for his help in the turbidimetric determination of hyaluronate lyase, and Dr. J. Estable and Mr. A. Esponda for their help in the biological investigation of histamine. This work was supported in part by the Rockefeller Foundation and by the Office of Scientific Research of the Air Research and Development Command of the U.S. Air Force under contract *AF* 49-638 (585).

Failure of Methylcellulose to alter the Growth of Walker Tumour 256 in Rats

Methylcellulose is a long-chained methyl ether of cellulose. Recent reports have associated regression of the transplantable Murphy–Sturm lymphosarcoma in rats with treatment by intraperitoneal injections of methylcellulose[1–4]. In the present investigation the same type of rats and treatment were used with the Walker tumour 256. As will be shown, no beneficial effect was noted in the parameters studied, namely, size of the tumour and longevity of the rats.

Adult female Sprague–Dawley rats averaging 140 g were divided into three groups of twenty each; size and age were similar. The methylcellulose was prepared as a 2·5 per cent aqueous suspension of 400 CPS methylcellulose. Intraperitoneal injections of 2 c.c. of the suspension were made three times per week (Monday, Wednesday, Friday)[1], starting 10 days before the subcutaneous transplantation of the tumour as a cell-suspension. Injections of methylcellulose continued so long as the animals remained alive in Group *A*, and for only two injections after tumour transplantation in group *B*. Group *C* received tumour but no methylcellulose. The tumour was measured every second day and the product of the longest and shortest dimension recorded.

Fig. 1 summarizes the findings; each point represents the average of the size of the tumours in the group.

In our laboratory, the Sprague–Dawley host has shown some degree of natural resistance to the Murphy–Sturm lymphosarcoma, but not to the Walker tumour. We have observed 10–20 per cent complete spontaneous regression of the Murphy–Sturm tumour, in various experiments; however, complete spontaneous regression of the Walker tumour has not been seen. We feel that methylcellulose may enhance a natural resistance already present in the host and which is sufficient in the case of the Murphy–Sturm lymphosarcoma to tip the balance in favour of the host. However, in the case of the Walker tumour any natural resistance which may exist is not strong enough to be expressed spontaneously and cannot be potentiated to that point by methylcellulose. The mechanism of action of methylcellulose is not clear, but, the Murphy–Sturm tumour being a homograft, an enhancement of the homograft rejection mechanism may be involved. The Walker tumour 256 is also a homograft.

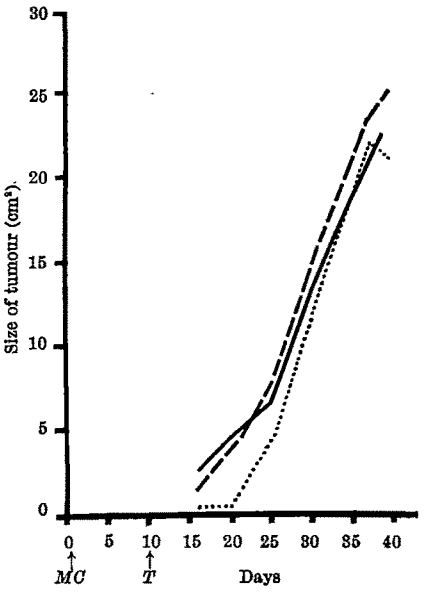

Fig. 1. Comparison of average size of tumours in methylcellulose-treated and non-treated groups. ——, Continuous treatment with methylcellulose (Group *A*). - - - -, Treatment with methylcellulose stopped after two injections post tumour transplantation (Group *B*). . . . . , Control, no methylcellulose (Group *C*). Arrow *MC* indicates start of methylcellulose injections. Arrow *T* indicates transplantation of Walker tumour

HAEMATOLOGY

Influence of the Erythroid Activity of the Bone Marrow on the Plasma Disappearance of Injected Erythropoietin in Dogs

The finding that plasma erythropoietin titre in patients with an aplastic or hypoplastic bone marrow was higher than in patients with haemolytic anaemias despite similar haemoglobin concentration led Stohlman to postulate that the plasma erythropoietin level is related not only to the severity of the stimulus but also to the degree of erythroid activity of the bone marrow[1]. Jacobson *et al.*[2] and Hammond *et al.*[3] have suggested that erythropoietin may be consumed or degraded by actively proliferating erythrocytic elements.

This report presents data on the rate of disappearance of erythropoietin from plasma of normal, erythropoietically stimulated (acute hypoxia) and erythropoietically de-

After this initial potentiation the antagonism to the effect of the sympathomimetic now appears and after large doses of prostaglandin it is of a progressive and irreversible nature.

To investigate the possibility that prostaglandins may occupy the adrenergic receptors, 'receptor protection' experiments were performed on the rat vas deferens. After obtaining regular cumulative dose-response curves to phenylephrine, one vas was exposed to PGE_1 alone and the other to PGE_1 in the presence of a high concentration of phenylephrine. Fig. 2 shows the results of such an experiment. Clearly, exposure to PGE_1 in the presence of a high concentration of phenylephrine confers no protection from the inhibitory effect of PGE_1. Indeed, the reverse is apparent. The presence of phenylephrine during the exposure to PGE_1 increases the rate of development of the inhibitory effect of the prostaglandin. It is suggested that a possible explanation for these observations is that the prostaglandin molecule does not itself occupy the adrenergic receptor but binds the sympathomimetic to the receptor. Repeated application of the sympathomimetic after exposure to prostaglandin would lead to a progressive elimination of receptor sites, accounting for the progressive depression in the maximal response of the preparation to the sympathomimetic. This mechanism, by increasing the affinity of the sympathomimetic for the adrenergic receptor, may also explain the initial potentiation of the effects of sympathomimetics after exposure to prostaglandins. Further work is in progress to examine this possibility.

PHARMACOLOGY

Venom of the *Megalopyge urens* (Berg) Caterpillar

The caterpillar of *Megalopyge urens* (Berg), commonly known as '*Bicho peludo*', is abundant in southern Uruguay in some years during February and March (Fig. 1). Its sting is feared because of the intense pain experienced by the victims. The black rigid pinking hairs (1 mm long) emerge from the papillae of the caterpillar among longer apatulated and white feathery hairs. There are several reports on the effect of *M. urens* venom in man and animals[1-4]. This work is concerned with the enzymatic and immunological properties of the venom and the electrophoretic separation of its different components.

All the experiments reported here were carried out with a venom solution obtained by irritating clean caterpillars in saline solution with a glass rod (one caterpillar per ml. saline). The venomous solution had a protein concentration varying from 0·3 mg per ml. to 0·6 mg per ml. and was stable for 1–2 weeks in the refrigerator. Concentration by vacuum evaporation or lyophilization of this solution led to loss of activity. The venom was of globulin nature.

Direct haemolytic activity was investigated *in vitro* according to Ganguly[5] and was moderately positive for human and dog red cells, slightly positive for rat and negative for guinea-pig red cells. Hyaluronate lyase activity was demonstrated in the venom by the Jaques bio-assay[6] and by a modification[7] of Mayer's turbidimetric method[8] (Fig. 2). The proteolytic enzyme was determined by digestion of casein[9], by Anson's assay for trypsin[10] and by digestion of 20 per cent gelatine containing 1 : 10,000 merthiolate at laboratory temperature for 45 h (Fig. 3).

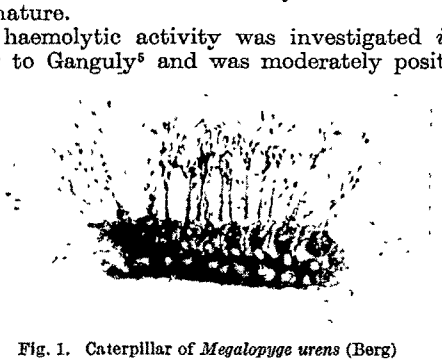

Fig. 1. Caterpillar of *Megalopyge urens* (Berg)

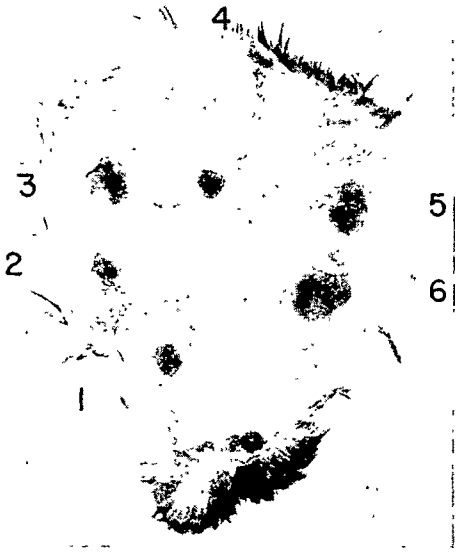

Fig. 2. Jaques's bio-assay for hyaluronate lyase with solution of venom from the *Megalopyge urens* (Berg) caterpillar: (1) 8 μl. *M. urens* venom, (2) blank; (3) 2 μg hyaluronate lyase; (4) 20 μg crystalline *Bothrops jararaca* venom; (5) 40 μl. 10-day-old *M. urens* venom; (6) 40 μl. fresh *M. urens* venom

Fig 3. Gelatine digestion by solution of venom from the *Megalopyge urens* (Berg) caterpillar: (1) blank; (2) 24-day-old *M. urens* venom; (3) 15-day-old *M. urens* venom; (4) fresh *M. urens* venom; (5) concentrated *M. urens* venom; (6) 0·5 mg/ml. crystalline *Bothrops jararaca* venom

The venom was analysed by filter-paper electrophoresis using a Spinco apparatus (model *R*) and 470 filter-paper (Schleicher and Schüll), a veronal buffer (*p*H 8·6), and ionic strength of 0·075. Separation was continued at 5 V/cm for 8 h. The strips were cut into thirty-two segments each 1 cm long, and these were carefully eluted with saline in separated test-tubes and the bands detected by the method of Lowry *et al.*[11] in a portion of the contents of each tube. The venom protein was separated into four fractions: 1, (fastest anodic mobility, 9 cm) with haemolytic activity only; 2, (anodic mobility, 5 cm) with hyaluronate lyase activity alone; 3, (origin) with proteolytic activity together with a very low haemolysin effect; 4, (cathodic mobility, 7 cm) unidentified protein.

Rabbits weighing 2 kg were immunized against the total venom with nine intravenous injections (by way of the

a direct effect which may be synergistic (tracheal chain preparation) or antagonistic (dioestrous guinea-pig and rat uterus, intestine) to the effect of the sympathomimetic substance. In these preparations, the doses of prostaglandins used were such that no direct effect on the tone of the preparation was apparent. In the guinea-pig uterus, for example, bath concentrations of $PGF_{2\alpha}$ as low as 10^{-12} g/ml. showed antagonism to the effects of noradrenaline, although a direct stimulatory effect of $PGF_{2\alpha}$ does not appear until bath concentrations of 10^{-8} g/ml. are reached. Moreover, the long-term effect of prostaglandins on responses to sympathomimetics, even after brief exposure to low concentrations, clearly distinguishes direct and indirect effects. In the rat vas deferens, no direct effect of prostaglandins is evident at concentrations up to 5×10^{-6} g/ml. PGE_1 although antagonism to the effect of sympathomimetics can be demonstrated at concentrations as low as 10^{-9} g/ml. For this reason the rat vas deferens was chosen for 'receptor protection' studies.

It was found that irrespective of the nature of the direct effect of the prostaglandin (stimulation, inhibition, or no effect), and irrespective of the nature of the response of the preparation to sympathomimetics (stimulation or inhibition), the net effect of the prostaglandin was to depress the response of the tissue to sympathomimetics.

Fig. 1 shows dose-response curves of the vasa deferentia of a rat where one is stimulated by adrenaline and the other by carbamyl-choline. One curve represents the effect of the stimulant before exposure to prostaglandin and the other the effect of the stimulant 90 min after exposure to PGE_1 for 5 min at a concentration of 4×10^{-6} g/ml. The responses to carbamyl-choline are potentiated. The dose-response curve shows a shift to the left and the maximal response of the preparation to carbamyl-choline is increased. The dose-response curve for adrenaline, however, shows a shift to the right with a depression of the maximal response. The extent of this depression increased with time and without further shift of the lower part of the curve, and after a further 40 min the maximal response was only 58 per cent of the original value. This effect on the dose-response curve is also characteristic of the action of PGE_1 on the responses of the vas to phenylephrine and noradrenaline. The antagonism cannot be reversed by increasing the bath concentration of the agonist, even up to molar concentrations.

Two further features of the effect of prostaglandins are apparent. The first response of the preparation to the sympathomimetic after exposure to prostaglandin may be potentiated (Curve *B* (ii) in Fig. 2) and this initial potentiation is seen in preparations which are relaxed by the sympathomimetic as well as in those which are stimulated.

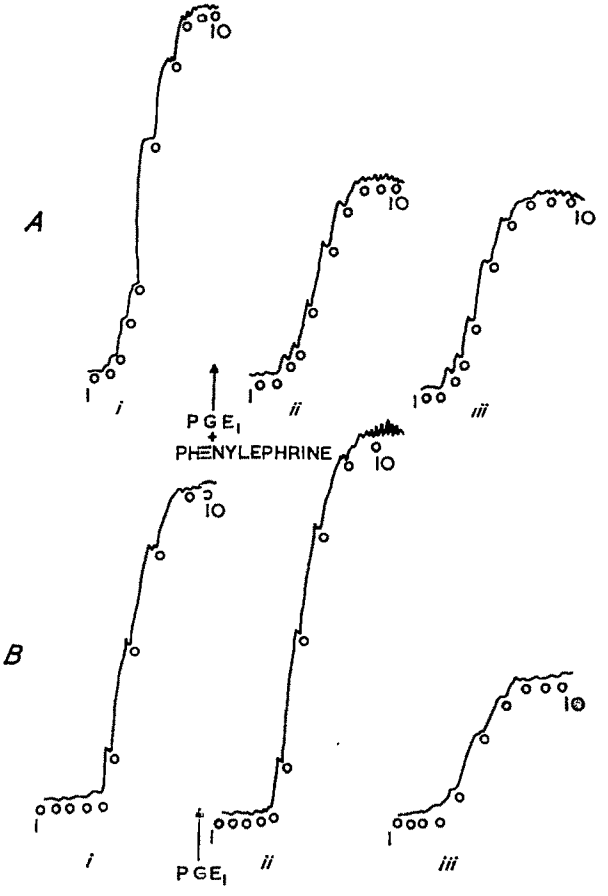

Fig. 2. Tracings of cumulative dose-response curves of the rat vas deferens stimulated by phenylephrine. The concentration of phenylephrine was increased by steps of (log 10)/3 after closing the tap leading to the organ chamber. The circles represent the points at which phenylephrine was added. The label 1 corresponds to a bath concentration of 10^{-7} M; label 10 to 3×10^{-6} M. Both preparations were exposed to PGE_1 (4×10^{-7} g/ml.) for 5 min, one in the presence of 10^{-5} M phenylephrine (*A*) and one in the absence of phenylephrine (*B*). Curves *A* (ii) and *B* (ii) were made 100 min after exposure to PGE_1, curves *A* (iii) and *B* (iii) were made 160 min after exposure to PGE_1

Table 1. Effects of Prostaglandins and Sympathomimetics on Various Tissues

Preparation*	Prostaglandin used†	Sympathomimetic and its effect	Effect of prostaglandin on response to sympathomimetic
Rat vas deferens (20)	PGE_1 (*nil*) $PGF_{2\alpha}$ (*nil*)	Phenylephrine (+) Noradrenaline (+) Adrenaline (+) Isopropylnoradrenaline (+)	Inhibition Inhibition Inhibition Inhibition
Rat colon (6)	PGE_1 (+) $PGF_{2\alpha}$ (+) $PGF_{1\beta}$	Noradrenaline (−) Adrenaline (−)	Inhibition Inhibition
Rat fundic strip (5)	PGE_1 (+) $PGF_{2\alpha}$ (+) $PGF_{1\beta}$	Noradrenaline (−)	Inhibition
Guinea-pig uterus (i) Dioestrous (stimulated by vasopressin) (3)	$PGF_{2\alpha}$ (+)	Noradrenaline (−)	Inhibition
(ii) Oestrous (in presence of a β blocking agent) (3)	$PGF_{2\alpha}$ (+) PGE_1 (+)	Noradrenaline (+)	Inhibition
Rat uterus (electrically stimulated) (6)	$PGF_{2\alpha}$ (+) PGE_1 (+) $PGF_{1\beta}$	Noradrenaline (−) Adrenaline (−)	Inhibition Inhibition
Guinea-pig tracheal chain (contracted by carbamyl-choline chloride 10^{-7} M–10^{-6} M) (3)	PGE_1 (−) $PGF_{2\alpha}$	Noradrenaline (−) Isopropylnoradrenaline (−)	Inhibition Inhibition

* Number of experiments in parentheses.
† Nature of direct effect in parentheses.

It is concluded that chloride ions are actively transported across the frog corneas and this ionic transport represents the only source of current across this membrane, and probably it is directly related to corneal hydration and transparency. The ATPase found in the frog corneas would seem to be different from that found in sodium transporting systems[6] and might not be related to the chloride transport found. Though this does not mean that chloride transport is not ATP dependent, it is possible that another mechanism might be involved in the transport of chloride across biological membranes.

Vanadium and Dental Caries

THE effects of trace elements other than fluoride on dental caries have recently received increased attention. The results of numerous investigations, reviewed elsewhere[1], have indicated that selenium is capable of increasing the susceptibility to caries, particularly when it is consumed during the formation of the teeth and incorporated into their structure. On the other hand, molybdenum appears to have a beneficial effect on caries[2].

In recent years, vanadium has been investigated as a caries-inhibiting trace element. Vanadium was found to decrease caries when given to hamsters and rats either during the time of tooth formation or post-developmentally[3,4]. However, further animal experiments failed to substantiate these findings[5,6].

The only investigation of the effect of vanadium on caries in man was conducted in Wyoming among children[7]. This State was selected because it contains widespread deposits of vanadium. For ascertaining the dietary intake of vanadium by the children, its concentration in water samples was determined. This was based on the premise that water is the main vehicle for vanadium ingestion in man, as is the case with fluoride. The majority of the water samples contained minute amounts of vanadium ranging from 0·03 to 0·09 p.p.m. with a few above the latter level. It was concluded that the consumption of water containing vanadium as low as 0·07–0·09 p.p.m. was responsible for decreasing dental caries in children as compared with those drinking water with vanadium at levels of 0·03–0·06 p.p.m.

In the light of recent findings, it appears that, in general, water does not constitute an important source of vanadium and that its concentration cannot serve as a reliable criterion of the total amount of this element ingested daily. An investigation of 194 public water supplies in cities located in forty-nine States was conducted by the U.S. Public Health Service. It revealed the presence of minute amounts of vanadium in the samples ranging from 0·0004 to 0·07 p.p.m. with a mean content of 0·006 p.p.m.[8]. In a second investigation by the U.S. Public Health Service, it was shown that from a total of 247 water samples taken from five major rivers (Ohio, Mississippi, Colorado, Missouri, Columbia) and the Great Lakes, vanadium was detected in only five samples[9]. No vanadium was found in the samples from the Ohio and Mississippi Rivers and the Great Lakes.

It is concluded that in epidemiological studies on the association between vanadium intake and caries, the concentration of this element in water alone cannot be relied on as an index reflecting the total amount ingested daily. It is known that the same is true with regard to selenium, even in seleniferous regions[10]. Other methods should be used for assessing the dietary vanadium intake in population groups.

Antagonism by Prostaglandins of the Responses of Various Smooth Muscle Preparations to Sympathomimetics

PROSTAGLANDINS are known to produce two types of effects on smooth muscle. First, they may produce direct and relatively short-lived effects, such as stimulation of the isolated uterus or relaxation of the isolated tracheal chain preparation. Secondly, in doses too low to produce a direct effect, they may produce a long-term potentiation of the effects of other stimulants. These two effects have been investigated in the isolated guinea-pig uterus[1]. The long-term potentiation of the effects of other stimulants which is induced by brief exposure of the guinea-pig uterus to low concentrations of PGE_1 or PGE_2 appears to be non-specific with respect to the potentiated stimulant, and can be demonstrated with a variety of stimulants including vasopressin, oxytocin and histamine, and also with electrical field stimulation[2]. The potentiating effect, however, is fairly specific to prostaglandins of the PGE series. This type of effect is not restricted to the guinea-pig uterus and can be demonstrated on the isolated rat colon or vas deferens (Fig. 1).

Another indirect long-term effect of prostaglandins of both the PGF and the PGE series is described here, and consists of a depression of the responses of various isolated smooth muscle preparations to sympathomimetic substances—to adrenaline, noradrenaline, phenylephrine, and isopropyl noradrenaline.

Some tissues in which this effect has been examined are shown in Table 1. In some of these, prostaglandins have

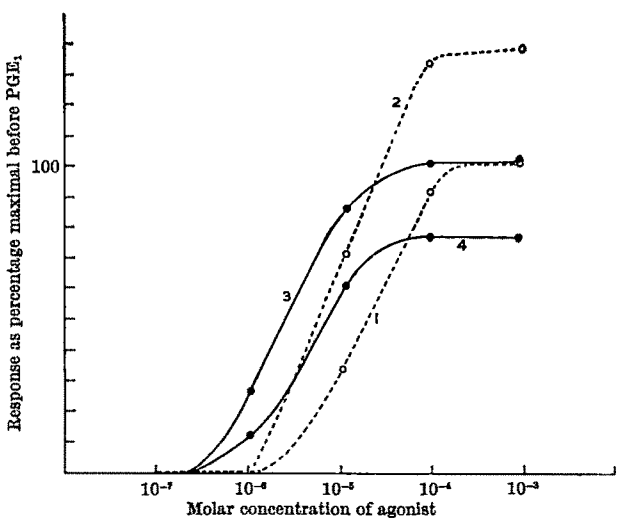

Fig. 1. Cumulative *in vitro* dose-response curves of rat vas deferens to carbamyl-choline (interrupted line) and adrenaline (solid line). Curves 1 and 3 were obtained before exposure to prostaglandin. Curves 2 and 4 were obtained 90 min after exposure for 5 min to PGE_1, at 4×10^{-6} g/ml.

PHYSIOLOGY

Asthma and Testosterone

It was previously shown[1,2] that testosterone is a powerful inhibitor of histamine and SRS* responses, and in view of the varying age incidence of status asthmaticus in the two sexes it was thought testosterone levels might have aetiological significance. Dutch workers have thought along similar lines[3]. Accordingly blood levels were measured in male and female subjects (by courtesy of Dr. J. Coghlan and Prof. Hudson) immediately after a severe attack. In two males the levels were 0·87 and 1·03 μg/100 ml. (high and one above normal: range 0·37–1·00) while in four females the levels were 0·13, 0·16, 0·19, and 0·29 μg/100 ml. (above normal: range 0·04–0·12). In another asthmatic subject, in the interval between attacks, the level was 0·24 μg/100 ml. (male), which is significantly low. I am now investigating the possibility that the level may be low in asthmatics, but that as a reaction to the stress of an attack, possibly associated with anoxia and hypercapnia, the levels rise high temporarily. Corticoid and also oestrin levels will be measured, as sometimes oestrins enhance histamine responses.

Active Transport of Chloride across the Cornea

The presence of an active transport of ions across the cornea has been postulated[1–3] in connexion with the loss of transparency of this membrane when it swells, after reduction of its metabolic rate or injury. The swelling and opacity, especially after exposure to cold solutions, is reversible and this has prompted the notion that an active ionic transport is performed by the cells of the epithelium or endothelium, dragging water out of the stroma to preserve the normal orientation of the fibrils.

The cornea of the American bull frog (*Rana catesbiana*) maintains a potential difference of 15–60 mV and produces short-circuit currents of 6–30 μamp/cm², when mounted as a membrane in Ussing's modified type of chamber[4]. The aqueous or endothelial side is positive and the tear or epithelial side is negative. The potential and the short-circuit current are mainly dependent on the presence of chloride ions in the aqueous side. As can be seen in Fig. 1, when all the chloride ions are replaced by sulphates in the fluid[5] bathing the corneas, the short-circuit current is markedly reduced; it recovers to control-levels, however, when chloride ions are again present in the fluid. The same effect is obtained if methyl-sulphate ions are used to replace the chlorides. The measurement of chloride fluxes with chlorine-36 in short-circuited corneas, as shown in Table 1, indicates that there is a net transport of chloride from the aqueous towards the tear side of the cornea. From 95 to 100 per cent of the short-circuit current measured could be computed as due to the chloride net transport, as shown at the bottom of Table 1. Sodium fluxes measured with sodium-22 indicate that no net transport of this cation is performed, since both unidirectional fluxes are similar. In these corneas chloride is secreted towards the outside, and then possibly sodium ions are dragged along passively, due to the potential difference. This salt movement could then induce water to follow it, keeping the hydration of the cornea at the normal level, and consequently preserving its transparency.

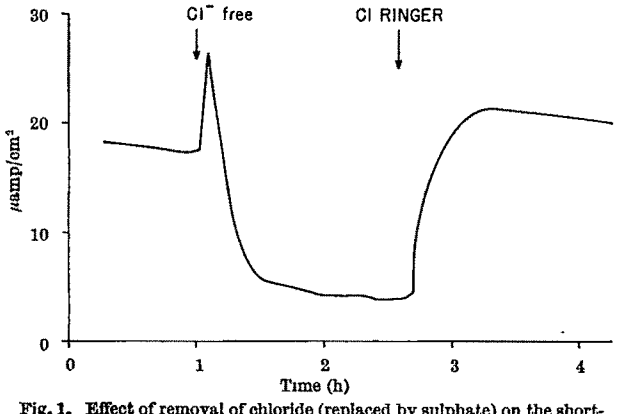

Fig. 1. Effect of removal of chloride (replaced by sulphate) on the short-circuit current produced by the isolated frog corneas

Table 1. Chloride Fluxes across Isolated Frog Cornea

Aqueous to tear side		Tear to aqueous side	
μEquiv./h/cm²	Short-circuit current (μamp/cm²)	μEquiv./h/cm²	Short-circuit current (μamp/cm²)
0·535	13·1	0·188	14·0
0·780	23·3	0·288	10 3
0 803	18·4	0·086	15 0
0 740	14·0	0·153	33·0
1·075	11·4	0·162	19·0
1·060	25·8	0·237	9 6
0 513	15·1	0 402	21·3
0·952	21·6	0 074	17·6
1·185	30 8	0·187	15 5
Mean 0 849	19·3	0 197	17·25

Chloride net flux = 0 849–0·197 = 0·652 μequiv./h/cm² Current measured = 18 2 μamp/cm². Current from chlorine transport = 17·5 μamp/cm².

When the chloride concentration is increased or decreased in steps of 10–20 mM of chloride in the inside, while regular fluid is kept in the outside or tear side, a saturation-type curve is obtained as the chloride concentration is plotted against the stable short-circuit current attained after each replacement. In double reciprocal plottings, straight lines are obtained as shown in Fig. 2, indicating saturation-type kinetics.

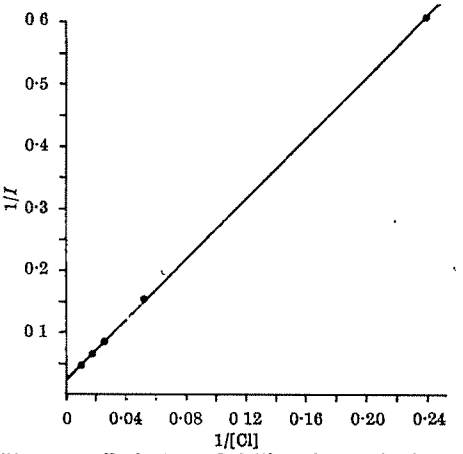

Fig. 2. Lineweaver–Burke type of plotting of short-circuit current (*I*) against chloride concentration in the fluid bathing the aqueous side of the frog cornea

The short-circuit current is sensitive to ouabain, but only at high concentrations, 10^{-4} M, and a definite drop of the current is observed only after a delay of about 1 h when the glucoside is added in the inside or aqueous side of the corneas. Though sodium ions move only passively across the corneas, the presence of these cations is necessary inside to maintain the potential.

Homogenates of the corneas exhibit ATPase activity in the presence of magnesium and in the absence of calcium. This magnesium-activated ATPase activity does not, however, show any affinity for sodium or potassium. The ATPase splitting activity is found in the microsomal as well as in the mitochondrial fraction of these corneas, and does not show any sodium, potassium or chlorine affinity. Ouabain does not affect the ATPase splitting activity of the preparations.

colonies grown on agar are grey-white and show in cross-section a typical plectenchymatic structure like that of a true sclerotium. As with *Claviceps paspali*, the mycelium of this strain grown in submerged culture has a cellular structure similar to that of a natural sclerotium. Ergotamine production in submerged culture occurred in a culture medium of high osmotic pressure of the following composition: Mannitol 20 per cent; peptone-Difco 3 per cent; tap water; final *p*H 6·2. The culture medium was sterilized for 30 min at 110° C. Cotton-wool plugged 500-ml. Erlenmeyer flasks containing 100 ml. of culture medium were used on a rotary shaker at 24° C (200 r.p.m., eccentric throw 10 cm). After 8–10 days the total alkaloid content from the broth and mycelium ranged from 800 to 1,400 μg/ml. (calculated as ergotamine). Chromatographic analysis of the alkaloids extracted from the culture medium showed ergotamine to be the principal component present.

Further Proof of Direct Oxygen Transfer by Carotenoids in Respiration and Photosynthesis

The hypothesis that carotenoids participate in oxygen transfer in photosynthesis was first put forward by Warburg and Krippahl[1], then by Cholnoky *et al.*[2]. Sapožnikov[3] observed increased production of violaxanthin (a diepoxide of lutein) in darkness with a corresponding decrease in lutein production. In illuminated medium the opposite reaction occurred. Hydroxylamine, a well-known inhibitor of photosynthesis, has been shown[4] to retard this light–darkness reaction. Blass, Anderson and Calvin[5] confirmed the work of Sapožnikov, but, although they observed the decrease of violaxanthin in light, they found no corresponding rise in the concentration of lutein. In these experiments, however, nearly equal specific radioactivity of lutein and violaxanthin was noted. This fact suggests an interrelationship between these two carotenoids in photosynthesis and respiration respectively. Recently, Saakov[6] gave a complete scheme of the biosynthesis of carotenoids and of their oxido-reduction reactions in photosynthesis.

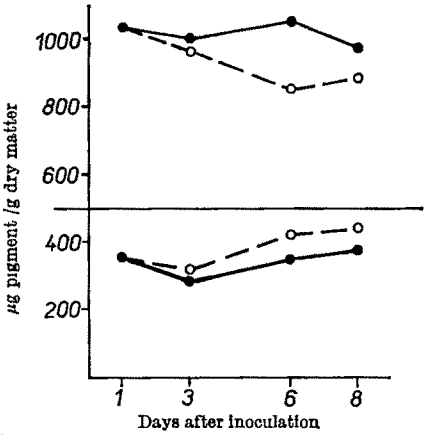

Fig. 1. Increase in violaxanthin content with corresponding decrease in lutein content in barley after infection with powdery mildew. Mean values of at least three determinations; maximal standard deviation for violaxanthin (bottom graphs): ±0·009; for lutein (top graphs): ±0·043. ●——●, Control plants; ○ — — ○, infected plants

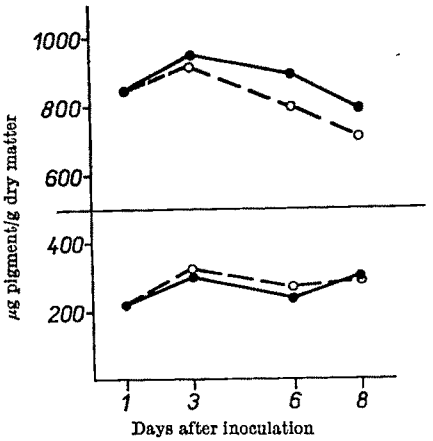

Fig. 2. Increase in neoxanthin content and decrease in β-carotene content in barley after infection with powdery mildew. Mean values of at least three determinations; maximal standard deviation for neoxanthin (bottom graphs): ±0 004; for β-carotene (top graphs): ±0 021. ●——●, Control plants; ○ — — ○, infected plants

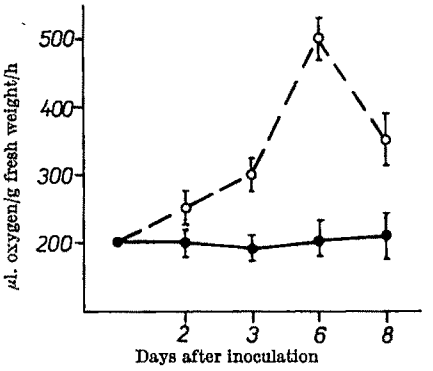

Fig. 3. Rise of respiration of barley after infection with powdery mildew. ●——●, Control plants; ○ — — ○, infected plants

During our investigations[7] of barley infected with powdery mildew (*Erysiphe graminis f.sp. hordei* Marchal, strain C_6) under standard conditions we observed increased content of violaxanthin immediately after infection with the fungus up to the sporulation time of the parasite. Together with the increase of violaxanthin content a corresponding decrease in lutein content was observed (Fig. 1). Increase of oxidized carotenoid with a corresponding drop in the content of the reduced form took place in the same phase of the disease, in which increased respiration of the host occurs. (Pigment analyses were made spectrophotometrically after thin-layer chromatography on silica gel.)

It may be mentioned that a decrease of β-carotene (mono-hydroxy-β-carotene) and a slight increase of neoxanthin (mono-epoxy-lutein) were also found during the period of increased respiration (Fig. 2).

These results may be regarded as further proof of direct oxygen transfer by carotenoids in photosynthesis and respiration.

I thank Mr. F. Frič for his assistance.

Each animal received a single dose of 0·2 ml. adjuvant intraperitoneally.

of the carbon from the blood stream by the reticulo-endothelial cells: although useful for comparison with other published work, it is not a linear index and it is more correct to express phagocytic activity as the reciprocal of *K*, since this gives a linear dose-response relationship ($Kr = 1/K \times 10^3$) and allows statistical analysis of the results[11].

It can be seen (Table 1) that both incomplete and complete Freund's adjuvant stimulate the phagocytic activity of the reticulo-endothelial system, but the complete adjuvant is a more powerful stimulant of phagocytosis than the incomplete. The levels of phagocytic stimulation produced by the incomplete adjuvant are similar after subcutaneous or intraperitoneal injection, but the complete adjuvant produces higher levels of phagocytic activity when given intraperitoneally rather than subcutaneously. It thus appears that the water-in-oil emulsion constituting the incomplete adjuvant acts as a weak stimulant of phagocytosis, and that the stronger reticulo-endothelial system stimulation produced by the complete adjuvant is due to the added *Mycobacterium butyricum*. These findings also suggest that the rate of absorption of the water-in-oil emulsion is the same following subcutaneous or intraperitoneal injection, but that the absorption of *M. butyricum* or its active principle is more effective intraperitoneally.

When a single intraperitoneal injection of 0·20 ml. of Freund's incomplete or complete adjuvant was given, it can be seen (Table 2) that, in both cases, phagocytic activity was significantly stimulated on the first day after injection, and that it remained stimulated on the second day, but declined to control level thereafter. It has been reported that Freund's adjuvant is most effective when administered at the same time as the antigen[12], although Muramatsu[5] has stated that it is most effective when given 5 days before the antigen. The present results suggest that the antigen should be given about the same time as the adjuvant.

A vast literature has accumulated over the past forty years on the nature and activity of substances capable of enhancing the immune response. This effect in the case of mineral particulate carriers and water-in-oil emulsions is generally accepted. More recently, bacterial endotoxins, lipopolysaccharide, lipid *A*, zymosan and oestrogen, all of which stimulate the phagocytic activity of the reticulo-endothelial system[9,13–15], have been shown to enhance markedly the primary antibody response to a variety of antigens[6,13,16,17]. The present results show that a water-in-oil emulsion type of adjuvant also stimulates the phagocytic activity of the reticulo-endothelial system and, since it has been demonstrated that phagocytosis of antigen is an essential step in the induction of the primary immune response[6,7], it seems likely that stimulation of phagocytosis is an important part of the mechanism of action of most adjuvants in enhancing antibody response.

HISTOCHEMISTRY

Rapid Staining of Juxtaglomerular Cell Granules and Renal Tubular Mitochondria for Light Microscopy

The methods in use for staining renal tissue for assessment of the juxtaglomerular index require either prolonged fixation or staining or both. We wish to report a technique which has the advantages of rapidity, staining contrast of the juxtaglomerular granules adequate for counting under

the light microscope, and the simultaneous preservation and staining of renal tubular mitochondria.

The stains most frequently employed for assessment of juxtaglomerular granulation are neutral dyes such as ethyl violet-biebrich scarlet (Bowie's stain)[1] or crystal violet-orange *G* (ref. 2). The reports of Wilson[3], Hartroft and Hartroft[4], Pitcock and Hartroft[1], Friedberg[5], and our own preliminary experiments with neutral dyes, indicate that the adequate demonstration of juxtaglomerular granules is a lengthy procedure occupying anywhere from 2 to 7 days, and that it is largely dependent on the use of fixatives containing potassium dichromate, followed by prolonged post-chroming. Staining alone requires at least 10–12 h. These methods of staining secretory granules, as well as the use of post-chroming in the demonstration of mitochondria for light microscopy, have been attributed to the action of potassium dichromate in rendering a wide variety of unsaturated lipids insoluble in lipid solvents[6].

We have carried out investigations into the staining of juxtaglomerular granules and renal tubular mitochondria in formalin-fixed tissue, using a procedure which avoids entirely the use of concentrated ethyl alcohol and xylene. Adult male white mice were killed with a blow on the head and their kidneys removed rapidly. Slices about 3 mm in thickness were fixed for 24 h in buffered 10 per cent formalin (*p*H 7·3) and the tissue was processed and embedded in polyethylene glycol ('Carbowax') and a polyvinylacetate resin according to a modification[7] of the method of Reid and Taylor[8]. Sections were cut at 2μ and 3μ and mounted on glass slides. The embedding medium was readily dissolved from the sections by brief immersion in methyl alcohol. Slides were stained for 2–2·5 min in a solution consisting of 25 drops of 1 per cent crystal violet or ethyl violet in 100 ml. of 20 per cent ethyl alcohol, followed by 5–10 sec in 100 ml. distilled water containing forty drops of 1 per cent neutral red or safranin *O*. The sections were rinsed in cold water and mounted directly using a water-soluble mounting medium.

This procedure results in considerably less tissue shrinkage than in control tissues embedded in paraffin and processed in a routine fashion, as judged by the size of the glomeruli and tubules and by the width of the intertubular tissue. Juxtaglomerular granules are stained an intense purple and are readily discernible as dark clumps at a magnification of × 80. The tubules are demonstrated chiefly through staining of the mitochondria which are easily recognized as blue-mauve rod-like filaments. Those in the distal tubules appear a deeper blue than those in the proximal tubules. Nuclei are stained red, and red blood corpuscles blue.

This method permits extremely rapid demonstration of the granulated cells of the juxtaglomerular apparatus, as well as the macula densa, since the cells of this structure are endowed with distinctly fewer mitochondria than the rest of the distal tubule and hence stand out in contrast (Fig. 1). The simultaneous rapid staining of renal tubular mitochondria offers unique opportunities for further studies in renal pathology and tends to confirm the preservation of phospholipid membrane systems by the present technique.

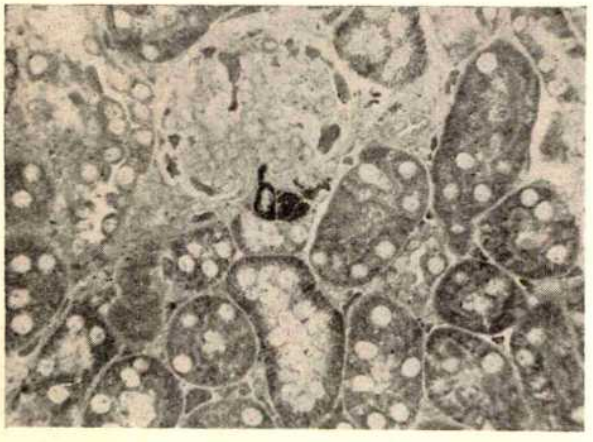

Fig. 1. Photomicrograph showing staining of *JG* granules and tubular mitochondria. Note paucity of mitochondria in macula densa. (Crystal violet–neutral red × *c.* 285)

Localization of Catecholamines in Brown Fat

The role of interscapular brown fat in non-shivering heat production is well established in new-born rabbits[1], new-born guinea-pigs[2], and during arousal from hibernation[3]. Heat is produced by the local oxidation of long-chain fatty acids. Regulation of heat production by the autonomic nervous system is strongly suggested by the fact that intravenous infusion of noradrenaline in physiological amounts stimulates heat production, and this heat production is abolished by pronethalol[1]. Stimulation of the cervical sympathetic chain in new-born rabbits causes a local increase in brown fat temperature above the deep-body temperature[4]. Fat cells contain a lipase which can be activated by catecholamines[5]. Brown fat from the interscapular region of adult rats contains a large amount of noradrenaline, which disappears rapidly after denervation or treatment with reserpine[6]. Brown fat is also richly innervated with non-medullated autonomic nerve fibres terminating in relation to fat cells[7].

Recent advances in the fluorescent method for the demonstration of catecholamines have opened new possibilities for their histological localization. Interscapular brown fat was examined from normal new-born rabbits, aged 24–48 h, and from littermates which had been given reserpine (0·2 mg/kg) 24 h previously. These tissues were then processed according to the techniques of Falck and Hillarp[8]. Sodium borohydride was used as a specific inhibitor for catecholamine fluorescence[9].

The characteristic green fluorescence of primary amines was found to be strongly present in the cytoplasm, but not in the cell nucleus of brown fat cells (Figs. 1 and 2). Individual nerve fibres showing green fluorescence were also found running between brown fat cells. Sodium borohydride treatment abolished this fluorescence. Moreover, both intracellular fluorescence and fluorescence of nerve fibres was very weak or absent in reserpinized animals.

In view of the previous work[6], showing a high concentration of noradrenaline in brown fat, the green fluorescence disappearing after reserpine treatment may be taken to indicate the presence of noradrenaline, both in autonomic nerve fibres and within brown fat cells. This would appear to be the first demonstration of the presence of catecholamines within brown fat cells.

Catecholamines have been shown to activate a lipase *in vitro* in adipose tissue with cyclic 3′5′-AMP probably acting as intermediate[5]. The observed cytoplasmic localization of a catecholamine, presumably noradrenaline,

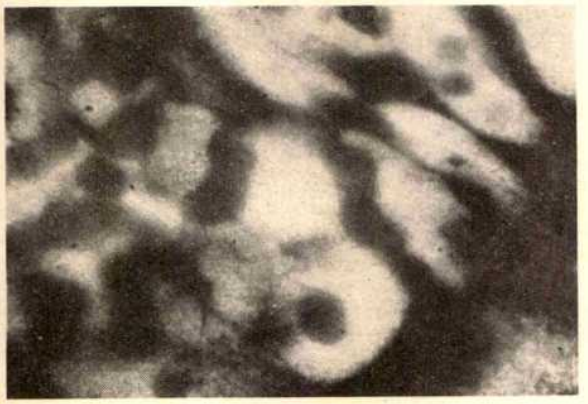

Fig. 2. The cytoplasm of the cells of brown fat shows a green fluorescence, whereas the nucleus does not fluoresce. (Falck-Hillarp method, × 550)

is clearly appropriate for activation of this lipase in the vicinity of fat droplets, leading to hydrolysis of triglyceride and subsequent oxidation of long-chain fatty acids.

Fatty Acid Composition of Triglycerides from Adipose Tissue

Brown adipose tissue has recently been shown to be the major site of non-shivering heat production in new-born rabbits[1] and to participate in heat production in the human new-born infant in a cool environment[2]. The major lipid in brown adipose tissue is triglyceride, which is present in numerous small droplets throughout the cytoplasm, and heat is produced by the local oxidation of this triglyceride after lipolysis[1]. White adipose tissue contains only a single large fat droplet, is almost entirely triglyceride[1] and its main function is the synthesis and storage of triglycerides and the release of free fatty acids into the blood stream when required. In view of these differences in function we have compared the fatty acid composition of triglycerides from brown and white adipose tissue in new-born and adult rabbits and in samples of brown and white adipose tissue obtained at autopsy in human new-born infants. The fatty acid composition of adipose tissue triglycerides is not significantly different in biopsy and autopsy samples[3].

Lipids were extracted from adipose tissue samples by the method of Folch, Lees and Sloane-Stanley[4], dried over anhydrous sodium sulphate, and the triglycerides isolated by means of thin-layer chromatography using Kieselgel *G* (Merck) activated at 105° C for 1 h and petroleum ether (40°–60° C)–diethyl ether–acetic acid (80:20:1) as solvent system. Fatty acids were methylated in 5 per cent hydrochloric acid in super dry methanol as described by Stoffel, Chu and Ahrens[5] and were identified by gas liquid chromatography using a 'Pan' chromatograph (Pye) with an argon ionization detector and polar (10 per cent polyethylene glycol adipate) and non-polar (5 per cent Apiezon grease *L*) stationary phases and comparison of retention times with known standards. Results are expressed as a percentage of total fatty acids detected.

Table 1 shows the results obtained. Substantial amounts of linoleic and linolenic acids are present in triglycerides of both brown and white adipose tissue from unsuckled new-born rabbits, suggesting transplacental passage of these essential fatty acids. The only significant difference between brown and white adipose tissue in the new-born rabbit appears to be a larger proportion of stearic acid and a lower proportion of palmitic acid in brown adipose tissue. No major differences exist between triglycerides of white adipose tissue from new-born and adult rabbits, apart from the increased palmitoleic in the new-born rabbit. Triglycerides from adipose tissue of both types from human new-born infants also contain linoleic and linolenic acids, but in smaller amounts. There is no significant difference in fatty acid composition of triglycerides from brown and white adipose tissue in the human new-born infant.

Comparisons of the fatty acid composition of brown and white adipose tissue triglycerides have been made in the adult rat[6] and the hibernating and non-hibernating bat[7]. In the rat, saturated fatty acids (myristic, palmitic and stearic) accounted for more of the triglyceride of brown adipose tissue than in white adipose tissue, but the differences were not large[5]. In the bat, both hibernating and non-hibernating, oleic acid was the major fraction,

Table 1. Fatty Acid Composition of Adipose Tissue Triglycerides

Source	Type	Percentage of total fatty acids							
		Myristic	Palmitic	Palmitoleic	Stearic	Oleic	Linoleic	Linolenic	Other
Interscapular adipose tissue (new-born rabbit)	Brown	2·2 ± 0·5	32·7 ± 2·2	5·8 ± 0·8	12·7 ± 1·2	27·3 ± 1·0	14·6 ± 1·8	3·5 ± 0·8	0·7

the concentration being three to four times greater than palmitic acid[6]. Human new-born adipose tissue triglyceride, both brown and white, contains more palmitic acid and less oleic acid than that reported by others[3,8–10] who have examined mixed lipids from adult subcutaneous white adipose tissue. Dietary differences may also account for these differences[10]. The distribution of fatty acids is closely similar to that reported for subcutaneous adipose tissue from three full-term human infants[8]. Triglycerides from human new-born adipose tissue differ from the rabbit chiefly in the much lower proportion of linoleic acid. This may reflect a difference in placental permeability to long-chain fatty acids. It is clear that the differences in function of brown and white adipose tissue are not accompanied by any consistent differences in the fatty acid composition of their triglycerides.

Laboratory facilities were provided by a grant from the Sir William Coxen Trust Fund.

Collagen, Elastic Tissue and Resorcin Fuchsin

In recent years several investigations[1–3] have thrown doubt on the specificity of resorcin fuchsin as a reliable stain for structures containing the protein elastin. These investigations have also indicated that some alteration in the state of collagen may cause the latter to react with this stain. Partridge[4] has suggested that this alteration is denaturation and the increase in reactivity which occurs with this change allows the protein to react with phenolic dyes. However, although resorcin fuchsin contains a phenol, the actual basic dyes used in the stain are not phenolic. Furthermore, it can be shown that certain fibres in connective tissue which stain with resorcin fuchsin but which are demonstrably different from the elastic tissue of the aorta, cannot be distinguished from normal collagen using the basic dyes from resorcin fuchsin without additives. Since denatured collagen has an isoelectric point of 4·8 compared with 7·5 (ref. 5) for the normal protein a simple basic dye should distinguish between the two. Such a result could not be obtained in the connective tissues mentioned. It follows, therefore, that connective tissue contains either three types of fibre reactive to resorcin fuchsin, namely, elastic tissue, denatured collagen and a previously undescribed fibre (Fig. 1), or some other aspect of collagen denaturation must be considered in accounting for the similarity in the staining reactions of elastic tissue and denatured collagen. It is the purpose of this communication to suggest that the loss of crystalline structure that occurs when collagen is denatured[6] accounts for this similarity and disposes of the need to postulate any other resorcin positive fibre in connective tissue.

Fig. 1 shows an aggregation of resorcin-positive fibres taken from the soft tissue beneath a denture that had been worn for many years. No such differential staining pattern could be observed when only the basic dyes, basic fuchsin or crystal violet, in aqueous solution were used to stain serial sections. In each case the addition of resorcin fuchsin caused a tangled pattern of dark staining fibres to appear resembling the appearance of Fig. 1. If, however, the elastic laminae of a young aorta were exposed to a simple solution of either of the two dyes for at least 4 h these structures could be clearly differentiated from the intervening collagen layers although the contrast was markedly inferior to that obtained with resorcin fuchsin. In addition to this difference these two tissues showed a difference in their relative affinity for iron. Ferric chloride is one of the additives in resorcin fuchsin, and Fig. 2 shows the result of soaking a section of aorta in 0·1 per cent ferric chloride followed by treatment with potassium ferrocyanide. The resorcin-positive elastic fibres in the aorta show no affinity for iron; the resorcin-positive fibres in the oral connective tissue showed an affinity equal to that of normal collagen, that is, no differential pattern could be obtained in the latter tissue.

Resorcin fuchsin contains, apart from the two basic dyes mentioned and the ferric chloride, resorcinol, ethyl alcohol and hydrochloric acid. Water is also present, as the alcohol used is industrial (70 per cent). Further variation of these components resulted in the observation that the behaviour of the whole stain could be duplicated by two different combinations of these additives. These two combinations, in the aorta, improved considerably the distinction that could be obtained using basic dyes only and in the dental tissue caused a differential pattern to appear similar to that obtained using resorcin fuchsin.

The first combination found to duplicate the behaviour of resorcin fuchsin was simply the addition of ferric chloride to an aqueous solution of basic fuchsin. These two components, when used separately, show up differences as already discussed between resorcin-positive fibres in the aorta and the experimental tissue; when combined, this property is lost. A probable explanation of this result may be based on the competition that exists between iron and basic fuchsin for the available carboxyl groups in a tissue section. According to Wigglesworth[7] iron co-ordinates with these groups in an extremely rapid reaction which takes preference over that with the positive charges of a basic dye. Although collagen reacts much more intensely with acid dyes under histological conditions, there is some reaction with basic dyes due to the fact that while the prevailing or net charge is positive, negative groups, mainly carboxyls, are present. The number of carboxyls in elastin is much smaller and the differentiation obtained between collagen and elastin by a simple basic dye in the aorta must be due to the differing modes of attachment, ionic or long-range in the case of the dye and collagen, short range (Van der Waals and/or hydrogen bonding) in the case of the dye and elastin. The effect of iron would be expected to improve differentiation between collagen and elastin by depressing the intensity of the collagen staining with basic dyes. This result is obtained in the aorta. In the experimental dental

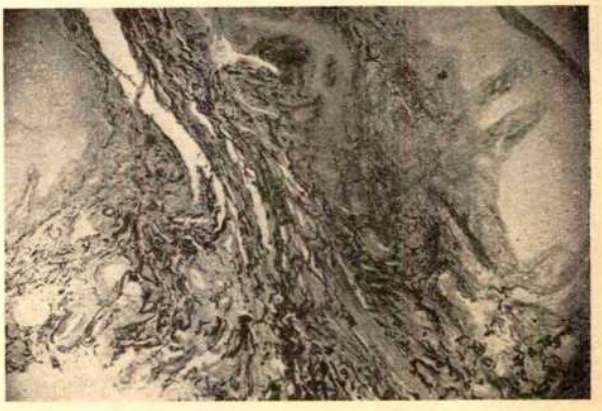

Fig. 1

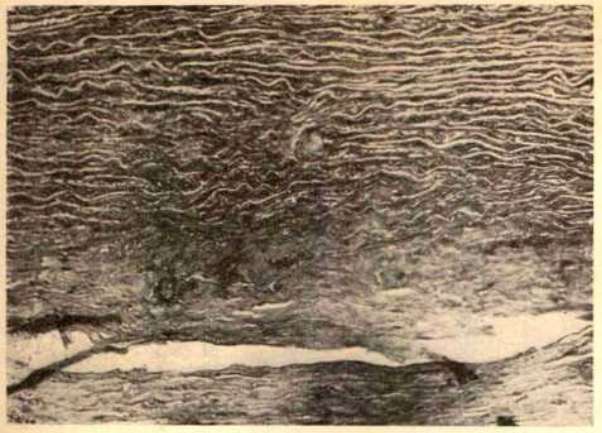

Fig. 2

tissue, however, fibres shown to be resorcin positive in serial sections are outlined by basic fuchsin combined with ferric chloride. A pattern only slightly inferior to that shown in Fig. 1 was obtained if the section was left in the staining bath for at least 4 h, a period well in excess of the 10 min usually required to colour a connective tissue section with basic fuchsin dissolved in water. In view of this time factor and the virtual elimination under these conditions of any reaction between charged groups, it is suggested that short-range forces become more prominent than is usual in simple staining procedures. Since short-range dye attachment[8] is governed more by variations in the degree of crystallinity at the surface of a dyeing substrate than charge distribution, it may be that the differential pattern in the dental tissue is the result of the basic fuchsin outlining the difference between amorphous and crystalline collagen. The long staining time supports this contention; short-range dye attachment takes much longer to reach equilibrium than long-range.

The second combination of additives found to duplicate the behaviour of resorcin fuchsin was a system composed of basic fuchsin, resorcinol and alcohol. The results obtained with this system were not sensitive to either the presence of water or various proportions of alcohol and water, provided some alcohol was present. Phenol could be substituted for resorcinol, as could pyrogallol, without affecting the result. Phenol, resorcinol and alcohol all have uses in the dyeing industry. Vickerstaff[8] lists phenol and resorcinol as additives that increase the pore size of fabrics, thus aiding short-range dye attachment. These additives are more efficient when the substrate is amorphous, crystalline areas being penetrated, if at all, much more slowly. Organic solvents[9] often facilitate dye attachment particularly in those cases in which the dye and a fibre possess similar charges and water is the main solvent. Provided the added organic solvent is more efficient at solvating the dye than water, the resulting redistribution of solvating forces in the system causes an increase in the intensity of dyeing with only a very small concentration of the organic compound present. The net effect is to decrease the effectiveness of the surface electrical barrier.

The simple experiment of adding alcohol to an aqueous staining solution of basic fuchsin caused an immediate increase in the intensity of the colour deposited on a tissue section and appeared to act in accord with the theory of solvent assisted processes. The presence of a swelling agent and alcohol in a solution of basic fuchsin will cause a double improvement in short-range attachment when a substrate is present and a single improvement in long-range attachment. In this system, therefore, crystalline amorphous differentiation is probably obtained in a manner opposite to that by which it is achieved using ferric chloride, namely the exaggeration of amorphous areas instead of long-range suppression. The combination of these two systems will be complementary since the iron reaction is predominant, limiting the action of alcohol in the complete system to short-range facilitation. The low *p*H in resorcin fuchsin is a further factor in favouring short-range attachment; the carboxyl groups are more effectively eliminated and the *p*H of maximum swelling of collagen is about 2·0 (ref. 10).

In summary, it is suggested that of the two principal changes reported to occur when collagen is denatured, the loss of crystalline structure is more important than the increase in electronegativity in relation to the specificity of resorcin fuchsin. Collagen and elastin should ideally be distinguished under ionic conditions and preferably by a reagent possessing no short-range attraction for either protein. Ferric chloride would seem to be a suitable reagent. Any connective tissue fibre giving a positive reaction to either resorcin fuchsin or any other elastic stain but which shows an attraction for iron similar to that of normal collagen is unlikely to contain a high proportion of the protein elastin.

PATHOLOGY

Erythrocyte Glucose-6-phosphate Dehydrogenase Activity in Haemoglobin H Disease

The occurrence of erythrocyte glucose-6-phosphate dehydrogenase deficiency in patients with haemoglobin H disease was first reported by Ramot, Sheba, Fisher, Ager and Lehmann[1] and Vella[2]. The former investigators considered the association in their patient to be coincidental, but Vella[2] reported that three of his six patients with haemoglobin H disease were deficient in this enzyme. Using the assay method of Kornberg and Horecker[3] we have determined the erythrocyte glucose-6-phosphate dehydrogenase levels in twenty consecutive, but unrelated, Chinese patients (eight males and twelve females) with haemoglobin H disease and found only one female to be enzyme deficient. The association of these two defects is therefore not so common as would appear from the report by Vella[2]. Although the number of patients investigated is not large, the incidence of erythrocyte glucose-6-phosphate dehydrogenase deficiency in haemoglobin H disease is probably not greater than that in the population —5·5 per cent in males[4] and 8·4 per cent in females (using calculations described by Allison[5] and assuming that approximately only 80 per cent of female heterozygotes are identified by the assay procedure[6]).

Table 1 shows that the mean erythrocyte glucose-6-phosphate level was significantly higher ($P < 0.001$) in patients with haemoglobin H disease than in non-anaemic controls (twenty males and twenty females). This is in agreement with Rigas and Koler[7], who reported that erythrocyte glucose-6-phosphate dehydrogenase levels were 2–3 times normal in two patients with haemoglobin

Table 1. Erythrocyte Glucose-6-phosphate Dehydrogenase Activity in Haemoglobin H Disease

Subjects	No.	Erythrocyte glucose-6-phosphate dehydrogenase activity: ΔO.D. per min per g haemoglobin	ΔO.D. per min per 100 ml. erythrocytes	ΔO.D. per min per 10^9 erythrocytes
Controls	40	9·6 ± 1·6 (6·4 – 14·9)	332 ± 52 (222 – 470)	0·290 ± 0·046 (0·194 – 0·449)
Haemoglobin H disease				
(*a*) Non-enzyme deficient	19	23·3 ± 5·1 (13·8 – 33·0)	645 ± 149 (405 – 977)	0·443 ± 0·124 (0·256 – 0·700)
(*b*) Enzyme deficient	1	2·8	79	0·055

Values shown are mean ± standard deviation. The range is in parentheses.

H disease and may be attributed to the presence in these patients of erythrocyte populations with a younger than normal mean erythrocyte age[7,8]. That the present series of patients with haemoglobin H disease had younger circulating erythrocytes can be adduced from their significantly elevated mean reticulocyte count of 3·5 ± 1·8 per cent (normal: 0·2 ± 0·2 per cent).

Tolerance of Phenylalanine after Intravenous Administration in Phenylketonurics, Heterozygous Carriers, and Normal Adults

Substances which have been introduced into the body by intravenous injection are eliminated from the blood in accordance with a mathematically definable pattern[1]. The results of heterozygote tests in phenylketonuria after oral administration of phenylalanine[2,3], however, do not make directly possible any estimation of the elimination rate from the blood. It is possible that, according to the configuration of the tolerance curves, the elimination of phenylalanine from the blood occurs at the same speed in controls as in heterozygous carriers[4]. It would be difficult to explain this mode if the velocity of elimination were primarily a function of the activity of phenylalanine hydroxylase[4].

The purpose of the investigation described in this communication was to estimate the rate of elimination of phenylalanine from the blood.

We tested seventeen healthy adults, nine heterozygotes, and six phenylketonurics. First we obtained a fasting specimen of capillary blood by means of a finger-prick. We then intravenously injected phenylalanine (sterile solution of 2·5 per cent of L-phenylalanine in water). The dose was about 50 mg per kg body-weight and the injection lasted about 10 min. Thirty minutes following the phenylalanine administration we collected further specimens at half-hourly intervals for a total period of 2·5 h. Assays of L-phenylalanine and L-tyrosine were performed on 0·1 ml. of blood by a modification of the enzymatic micro-method of La Du *et al.*[5] (for details of the modification see ref. 6). The phenylalanine-loading procedure was well tolerated and we did not observe any sympathomimetic response.

The semi-log graph of the phenylalanine concentration between 30 and 150 min after administration presents a straight line which complies with the general formula of a mono-molecular reaction.

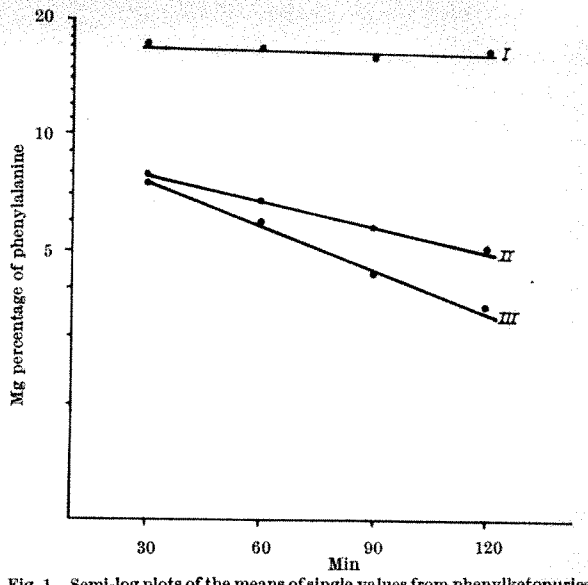

Fig. 1. Semi-log plots of the means of single values from phenylketonurics (I), heterozygotes (II), and normal adults (III). The mean of the fasting values in group I was 7·9 mg per cent; in group II, 1·7 mg per cent; in group III, 1·3 mg per cent

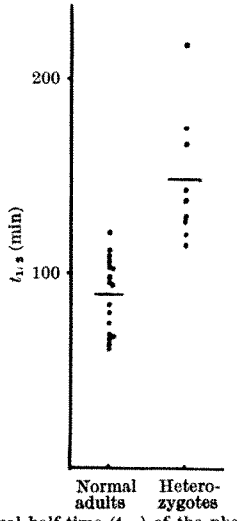

Fig. 2. The biological half-time ($t_{1/2}$) of the phenylalanine elimination from the blood of normal adults and of heterozygous carriers

Table 1 shows the mean time of elimination to the half concentration ($t_{1/2}$) and the mean disappearance constant (k), calculated from the general equation of a mono-molecular reaction.

In Fig. 1 the means of single values from these three groups have been plotted against time on a semi-log basis; Fig. 2 gives the $t_{1/2}$ values for the various tests with normal individuals and heterozygotes.

These results show that the heterozygotes have a significantly smaller rate of elimination than do the normal individuals. In phenylketonurics there was no great decline of phenylalanine during the test. The activity of the phenylalanine hydroxylase is, therefore, in all probability one of the limiting factors of the elimination rate of phenylalanine.

Recently, Nelson[4] raised the question concerning the phenylalanine tolerance tests for heterozygous carriers of

Table 1. Mean Values of $t_{1/2}$ ± Standard Error

	No.	$t_{1/2}$ (min)	k (per cent/min)
Adults	17*	88·7 ± 19·4	0·785 (range 0·573–1·14)
Heterozygotes	9*	148·1 ± 32·6	0·468 (range 0·318–0·602)

* The differences of the mean values of $t_{1/2}$ are significant according to the t-test ($P < 0·001$).

Table 2. MEAN TYROSINE-LEVELS ± STANDARD ERROR IN MG/PER CENT

Time after administration (min)	0	30	60	90	120
Normal adults	0·85 ± 0·60	1·55 ± 0·77	1·93 ± 0·42	2·01 ± 0·53	1·66 ± 0·42
Heterozygotes	0·90 ± 0·33	1·30 ± 0·62	2·00 ± 0·62	1·60 ± 0·07	1·77 ± 0·60
Phenylketonurics	0·10 ± 0·06	0·27 ± 0·26	0·20 ± 0·22	0·24 ± 0·21	0·32 ± 0·32

The standard error in this concentration range is high (ten assays from an individual: 0·83 mg per cent ± 0·49).

phenylketonuria. He suggested that the substantially higher phenylalanine-level in the heterozygote and in the phenylketonuric after oral phenylalanine loading was due to a difference in volume of the distribution of phenylalanine between these two groups. After intravenous injection of phenylalanine we found that the blood level of the control and the heterozygous group increased almost to the same extent. There was a slightly greater increase in blood-level in the case of phenylketonurics, but this increase was probably not a genuine one, as was found when the concentration was calculated at zero time from the semi-log plot.

An increase in the blood tyrosine-level was found in normal individuals as well as in heterozygotes. The dose of phenylalanine administered did not suffice, however, to identify a heterozygous state by an increase in the tyrosine-level (Table 2).

Estimation of the elimination rate after an intravenous load of phenylalanine may serve as a test for heterozygotes. due to the fact that the elimination in heterozygotes and in normal adults proceeds at different speeds. Some overlap, however, between normals and heterozygotes may occur in adults.

Furthermore, during the early days after birth the phenylalanine elimination may be markedly delayed[7]; thus during this period it is not possible to test for heterozygotes by this method.

RADIOBIOLOGY

Interphase Death and Related Biochemical Radiation Effects in Murine Leukaemia Cells

WITHIN a few hours after X-irradiation with sub-lethal doses, cytological and biochemical changes become demonstrable in the lymphocytes of the thymus and other lymphatic tissues.

The early death of lymphocytes occurring in the period after irradiation when cell division is inhibited (mitotic delay) is often referred to as 'interphase death'[1] as distinguished from cell death associated with mitosis (mitotic death) which occurs in other cell types.

It is frequently difficult to evaluate whether the biochemical disturbances precede the cellular degeneration as reflected by nuclear pyknosis and karyorrhexis. Some of the biochemical radiation effects, for example, the loss of cations from the nucleus[2], the decrease of sulphydryl groups in thymus nuclei[3] and the inhibition of nuclear oxidative phosphorylation[4,5], have been classified among the few early biochemical radiation effects which seem to precede the occurrence of morphological signs of cell damage.

Nuclear oxidative phosphorylation and its radiobiological implications have been the subject of our investigations in the past few years[5,6]. Recently we have investigated nuclear oxidative phosphorylation in three different transplantable lymphosarcomata and one myeloid leukaemia in mice. Certain findings concerning the cytological and biochemical effects of X-irradiation in these tumours and in rat thymus will be presented briefly here. Other aspects of these investigations have already been published[7].

The experiments were carried out with three different transplantable lymphosarcomata from the *C57BL/Rij*, *CBA/Rij* and (*CBA/Rij* × *C57BL/Rij*)F_1 mouse, respectively, and a myeloid leukaemia from the *RF* mouse. Only those leukaemic spleens were used in which the majority of cells consisted of leukaemic ones. Oxidative phosphorylation was measured at intervals after whole-body irradiation in the nuclei and in the mitochondria isolated from the leukaemic spleens and normal thymus tissue. The mode of cell death was identified in routinely stained histological sections from the same tissues.

Important differences between the radiation responses of the various cell types were found. According to the biochemical effects observed, the cells can be divided into two groups. In the first group, which includes thymic lymphocytes, myeloid leukaemic cells and *C57BL* lymphosarcoma cells, inhibition of nuclear ATP synthesis is observed within 2 h after irradiation with 900 r. (Fig. 1, group I). In thymus this inhibition is even more pronounced[5] and seems quite distinctly to precede cell death as judged by morphological criteria. In these three cell types mitochondrial phosphorylation is also depressed at an early stage, although the maximum inhibition seems to occur slightly later than that observed with nuclear ATP synthesis.

In the other group consisting of the *CBA* and F_1 lymphosarcoma cells, inhibition of nuclear oxidative phosphorylation develops later, that is between 8 and 24 h after irradiation, concurrently with the appearance of cytological changes. Mitochondrial oxidative phosphorylation is not disturbed in these cells even at the time when cellular disintegration is well advanced (Fig. 1, group II).

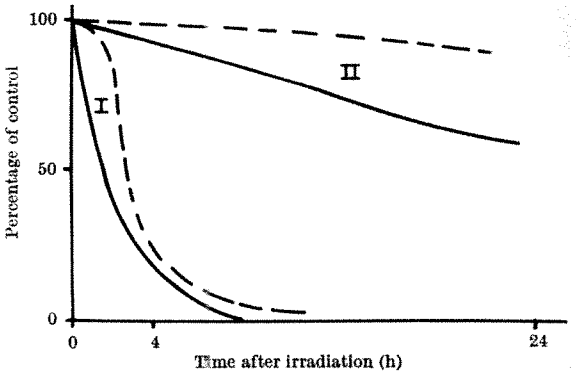

Fig. 1. Effects of 900 r. whole-body irradiation on oxidative phosphorylation. Averages of results obtained with thymus, myeloid leukaemia and *C57BL* lymphosarcoma (I) and with F_1- and *CBA* lymphosarcoma (II). ——, Nuclear oxidative phosphorylation; - - - - -, mitochondrial oxidative phosphorylation

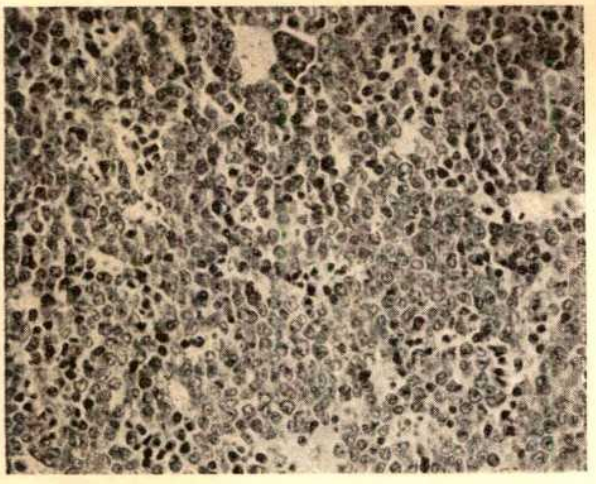

Fig. 2. Interphase death of murine myeloid leukaemia cells. Leukaemic spleen 2 h after 900 r. whole-body irradiation. Note nuclear pyknosis and homogenization of chromatin. Mitotic activity is completely absent. (Haematoxylin-eosin, × 150)

These results suggest that the pattern of biochemical changes seems to be specifically related to the mode of cell death after irradiation. As do normal lymphocytes, many of the myeloid leukaemic cells and *C57BL* lymphoma cells die in interphase (Fig. 2) while interphase death was much less apparent or even absent in the *CBA* and F_1 lymphosarcomata[8].

This relation had led us to postulate a biochemical basis of interphase death: cells in which radiation induces a rapid inhibition of both nuclear and mitochondrial oxidative phosphorylation may die in interphase as a consequence of energy exhaustion. When mitochondrial and nuclear oxidative phosphorylation remains relatively unaffected, the cells survive until the next mitosis.

Of special interest is the finding that interphase death is apparently not restricted to lymphoid cells (normal or leukaemic) but also occurs in an entirely different cell line: a myeloid leukaemia cell.

BIOLOGY

Secretion of the Thiocyanate Ion by the Nasal Gland of the Adelie Penguin

Analysis of the secretion from the nasal gland of marine birds indicates that the secretory mechanism is highly specific for sodium and/or chloride. Only very small amounts of potassium, magnesium, or sulphate normally appear in the secretion[1]. It was therefore of interest to determine how the secretory mechanism would behave in the presence of an anion which has roughly the same physical–chemical properties as chloride.

Thiocyanate space experiments performed during an investigation of the salt and water metabolism of the Adelie Penguin provided an opportunity to determine to what extent this ion, which does not normally occur in appreciable quantities in the plasma, would be excreted by the nasal gland. Consequently, the secretion from birds which had been given a thiocyanate injection and then 'salt loaded' was analysed for both thiocyanate and chloride.

Table 1 shows the results which were obtained from three sets of samples. It is seen that the concentration of thiocyanate in the nasal gland secretion is 6–7 times as great as the concentration of this ion in the plasma. After thiocyanate analysis, insufficient plasma remained for the chloride analysis. However, data from other experiments on 'salt-loaded' penguins indicate that an estimation of the plasma [Cl^-] at about 115 m.equiv./l. is justified. The ratio of secretion concentration to plasma concentration (S/P ratio) for thiocyanate is then seen to be quite similar in magnitude to that for chloride.

In order to eliminate the possibility that the salt gland was itself producing the thiocyanate ion in the course of its metabolic work, secretion was analysed from salt-loaded but not thiocyanate-dosed birds. In no case was there any indication of the presence of the ion.

The salt-secreting nasal gland has been referred to on occasion as "a gill in the nose". This comparison with the salt-secreting function of the marine teleost gills is not unwarranted. The first studies which demonstrated how marine fish maintain body fluids hyperosmotic to their environment without producing hypertonic urine involved determinations of chloride concentration[2,3]. The cells supposedly performing the transport of the salt from the blood into the sea were consequently termed 'chloride cells'. More recent work on ion transport mechanisms in general indicates that the term 'sodium cells' would be more apt.

Electrophysiological investigations have led to the view that the active transport of sodium chloride probably involves a sodium pumping mechanism and a passive diffusion of chloride. The studies which have been reported from the laboratories of Ussing[4] and Giebisch[5] have shown rather conclusively that it is the movement of sodium ions which constitutes the energy-consuming transport in the frog skin and in the proximal tubules of the kidney of *Necturus*. Hokin and Hokin[6] have presented evidence suggesting not only that it is sodium which is being pumped by the nasal gland of the albatross, but also that it is phosphatidic acid which serves as the cation carrier. Thesleff and Schmidt-Nielsen[7] have attempted a direct attack on the electrophysiology of the salt gland. Owing to the extensive folding of the membranes of the salt gland cells, intracellular potentials could not be reliably determined. It was found, however, that potential positive with respect to the homolateral jugular vein appeared in the duct of the gland at the time of secretion. This they interpreted as indicating that the potential was due to the active transport of the positive sodium ion from gland cell into duct lumen. Strophanthin, known as a sodium pump-blocking agent, blocked secretion and abolished the potential.

Table 1. Secretion of Thiocyanate by the Nasal Gland

Bird No.	Plasma SCN^- conc. (m.equiv./l.)	Secretion SCN^- conc. (m.equiv./l.)	S/P ratio	Secretion Cl^- conc. (m.equiv./l.)	Est. S/P ratio
1	0·70		6·1		
		4·29		748	6·5
		4·09	6·5	714	6·2
	0·63				
		4·05		715	6·2
		3·92		690	6·0
		4·02	6·5	756	6·6
	0·50				
2	0·65		6·6		
		4·27		748	6·5
		4·05	6·2	784	6·8
	0·65				
		3·99		758	6·6
		3·99		754	6·6
		4·02	6·8	614	5·3
	0·59				
3	0·69		7·1		
		4·92		756	6·6
		4·94		750	6·5
		4·10		608	5·3
	0·58		7·1		

In the light of these findings, the secretion of thiocyanate by the nasal gland at S/P ratios comparable with those of chloride is explained as a passive diffusion of the SCN^- ion. The equivalent conductivity of the thiocyanate ion at infinite dilution and 18° C is 57·4 ohm^{-1} cm^{-1} $equiv.^{-1}$ litre while that of chloride is 66·3 (Eichler, ref. 8. Values from the work of Landolt-Börnstein). The difference between the conductances of these two ions is 8·9. Information is not available on the conductance of the anions alone at higher concentrations. The difference in equivalent conductance of potassium thiocyanate and potassium chloride solutions, however, changes only slightly over the range of 0·1 m.equiv./l. to 500 m.equiv./l. (ref. 9). As a first approximation, the electrical requirements of the system could be as satisfactorily met through the diffusion of SCN^- as through that of Cl^-.

A report by Carey and Schmidt-Nielsen[10] indicates that some discrimination may be exercised by the gland on the anionic composition of its secretion. They found that the S/P ratio for iodide was about 2·5 as compared with about 6 for that of chloride in the herring gull. The S/P ratios in the Adelie for both chloride and thiocyanate were mostly slightly greater than 6. It would appear that the hydrated ionic radius is probably not the determining factor since the conductivity of iodide is about the same as that of chloride.

Strain Differences in Mouse Mammary Tissue Sensitivity to Prolactin and Somatotrophin in Organ Culture

THE lactogenic activities of ovine prolactin and bovine somatotrophin have been investigated in several strains of inbred mice, and a spectrum of responses was reported[1,2]. Prolactin was lactogenic in all strains, with some variations in sensitivity encountered. On the other hand, whereas somatotrophin showed considerable activity on tissues from some strains, other strains were much less reactive, and a single strain was completely unresponsive to the lactogenic effects of this hormone.

Two strains showing the extremes of responsiveness to somatotrophin, *C3H* (highly sensitive to somatotrophin) and *A* (refractory to somatotrophin), were later examined both in mammary transplantation studies[3] and in organ culture[4]. The results of these investigations clearly demonstrate that their differential sensitivity lies in the mammary tissues themselves and thus must reflect strain-specific tissue responsiveness.

Our observations on hormonal sensitivity *in vitro* have now been extended to several strains of mice other than *C3H* and *A*. This communication reports the responsiveness of *DBA*, *C3Hf*, *BALB/c*, and *C57BL* mammary tissues both to prolactin and to somatotrophin in organ culture. Comparison is made with the responses obtained in *C3H* and *A* mammary tissues in organ culture and with the differential strain sensitivity reported previously *in vivo*.

Mammary tissues for explantation were taken from nulliparous pregnant female mice from the following inbred strains: *DBA/2NCrgl*, *C3Hf/Crgl*, *BALB/cCrgl* and *C57BL/Crgl*. All mice were in the second week of pregnancy (10–13 days), at a time when the mammary alveoli are small and non-secretory, with few or no lipid vacuoles, and show no stainable material in the lumina[4].

The organ culture procedure has been described[4,5]. Synthetic basal culture medium 199 was supplemented with insulin, 5 μg/ml., aldosterone, 1 μg/ml., and either ovine prolactin (C. H. Li), 1–4 μg/ml., or bovine somatotrophin (C. H. Li), 2–10 μg/ml. Approximately 8–16 mammary explants from 4–5 mice from each strain were cultured with each concentration of each pituitary hormone. After 5 days in culture the tissues were prepared for histological examination and graded as previously described[4], according to the level of secretory activity attained. Particular attention was directed to the number of explants in each series showing maximal secretory responses: alveolar distension three to four times greater than in the initial control tissues, lipid vacuoles in most alveolar cells, and large amounts of stainable secretion in alveolar lumina[4].

A prolactin concentration of 1 μg/ml., capable of initiating maximal secretion consistently in *C3H* tissues, produced comparable effects in only 75, 60, 47 and 36 per cent of tissues from *DBA*, *BALB/c*, *C3Hf* and *C57BL* mice, respectively. This concentration of prolactin has no secretion-stimulating effect in tissues from *A* mice.

Tissue responsiveness was somewhat greater with 2 μg/ml. of prolactin; with 3 μg/ml., maximal responses were obtained in all *DBA*, *BALB/c*, and *C3Hf* tissues. *C57BL* mammary tissues, on the other hand, showed only 50 per cent maximal secretion even with 3 μg/ml. of prolactin. At 4 μg/ml., the responsiveness was increased to 86 per cent, a result comparable with that obtained in *A* tissues by this concentration of prolactin.

The mouse strains used may thus be ranked in the following order of decreasing sensitivity to prolactin: $C3H > DBA \simeq BALB/c \simeq C3Hf > A \simeq C57BL$. Except for the position of *BALB/c* mice in rank order, these results follow the general pattern observed *in vivo*: $BALB/c > C3H \simeq DBA \simeq C3Hf > A \simeq C57BL$ (taken from Nandi and Bern[1], Table 4). The high sensitivity of *BALB/c* mice to subcutaneous administration of prolactin is interesting, inasmuch as *C3H* tissues show the highest sensitivity *in vitro*. It should be mentioned, however, that prolactin also causes an increase in body-weight of *BALB/c* mice but not of other strains[1]. The relationship between the effects of prolactin on body-weight and mammary gland responsiveness is not at all apparent, but if the two effects are, in fact, causally related, then it is not surprising that *BALB/c* mammary tissues *in vitro* should fail to respond as *in vivo*.

A somatotrophin concentration of 2 μg/ml., capable of initiating consistent maximal secretion in *C3H* tissues, had corresponding effects in 78 per cent and 53 per cent of *DBA* and *C3Hf* tissues, respectively. As in *A* tissues, this concentration of somatotrophin caused no secretory response in *BALB/c* or in *C57BL* tissues. Consistent maximal responses could be obtained in *DBA* tissues by 3 μg/ml., whereas *C3Hf* tissues required at least 5 μg/ml. of somatotrophin for similar responses.

In contrast, 3, 4 and even 5 μg/ml. of somatotrophin had comparatively less secretory effect in tissues from *BALB/c* and *C57BL* mice. The responsiveness of these latter two strains could be increased to 100 per cent and 86 per cent, respectively, by 10 μg/ml. of somatotrophin, a concentration five times that optimally effective in *C3H* mice. Only 40 per cent maximal secretion was obtained in *A* tissues by 10 μg/ml. of somatotrophin. Thus, although *BALB/c* and *C57BL* tissues were somewhat more responsive to somatotrophin than *A* tissues, they were considerably less responsive than tissues from *C3H*, *DBA* and *C3Hf* mice.

In summary, the several mouse strains can be arranged in the following order of decreasing sensitivity to somatotrophin: *C3H* ≅ *DBA* > *C3Hf* > *BALB/c* ≅ *C57BL* ≫ *A*. These results follow the general pattern of responsiveness observed *in vivo*: *C3H* ≅ *DBA* > *C3Hf* ≅ *BALB/c* ≅ *C57BL* ≫ *A* (taken from Nandi and Bern[1], Table 3), and in both situations, mammary tissues from strain *A* mice may be considered refractory to somatotrophin.

It may be noted that although the strain differences in hormonal sensitivity *in vitro* in general compare well with observations *in vivo*, the patterns are not absolutely identical. For example, strains *C3Hf*, *BALB/c*, and *C57BL* mice respond to the same degree to somatotrophin *in vivo*; however, in organ culture *C3Hf* tissues were more responsive to somatotrophin than were tissues from *BALB/c* and *C57BL* mice.

The possibility that contamination with prolactin can account for the lactogenic activity of somatotrophin has already been discussed[4], and the question remains open until absolutely purified somatotrophin preparations are available. However, several other preparations of bovine somatotrophin have since been examined in organ culture and found capable of initiating mammary secretion in *C3H* mice but not in *A* mice[6]. Pigeon-crop and immunological assays of these preparations indicate less than 1 per cent prolactin contamination. The present data, therefore, continue to support the view that bovine somatotrophin possesses lactogenic activity independently of its contamination with prolactin but that this inherent activity is apparently limited to certain strains of mice. Barnawell[7] has found no stimulation of secretion ascribable to bovine somatotrophin itself in cultured mammary tissues from two rat strains, hamster, guinea-pig, rabbit and dog.

Further investigations are now in progress to determine whether somatotrophins from various non-bovine species are also lactogenic in mice.

I thank Prof. H. A. Bern, Dr. S. Nandi and Dr. J. J. Elias for advice. I also thank Miss L. Pissott and Miss D. Brown for their assistance and Prof. C. H. Li for the prolactin and somatotrophin. This work was supported by U.S. Public Health Service grants *CA*-05388 and 5-*T*1-5045.

Interspecific Spore Inhibition in the Cellular Slime Moulds

Experiments were designed by one of us (H. M. S.) to determine whether or not there was any kind of competition between different species of slime mould when they were inoculated in the same culture dish. If *Escherichia coli* (as a food source) was spread with an inoculation loop over the surface of non-nutrient agar[1] in a Petri dish and approximately equal numbers of spores from two species of slime mould were mixed in one small spot, then invariably only one of the species developed (either in the light or in the dark); the second species appeared to be completely inhibited. Using this method, the following hierarchy of inhibition was established: *Dictyostelium purpureum* (No. 2) > *Polysphondylium violaceum* (No. 6) > *D. discoideum* (No. 1) > *D. mucoroides* (No. 2). This method was also attempted using the wild type of strain No. 6 of *D. mucoroides* and a small mutant derived from the same strain. In this case also, one form (the wild type) completely inhibited the development of the mutant.

In an attempt to make the tests more quantitative, quite conflicting results were obtained and the difference in the techniques provided a clue to the mechanism of competitive inhibitions. With this second method, the spores were suspended in distilled water, counted, centrifuged down and again placed on a small spot as in the previous method. Here, no matter what combination of species was used, equal development was evident in the first few days; there was no inhibition.

The explanation of this apparent conflict came from some experiments that were in progress independently in the same laboratory (C. C.). A few years ago Russell and Bonner[2] showed that densely plated spores had a far lower percentage germination than sparsely plated spores, suggesting the presence of a spore germination inhibitor. This has now been shown to be the case. If spores of *D. discoideum* are washed four or five times with distilled water they will show more than 95 per cent germination at very high densities. It is even possible, after removing the inhibitor from the spores, to concentrate it by boiling, and a very low percentage of spores placed in such a concentrate germinates, even when they are sparsely plated.

From this evidence we may conclude that the germination inhibitor is the effective agent in preventing growth of one species when the spore mixtures are made in dry and concentrated conditions. The inhibition can be removed either in a single species or in mixtures of species by washing or dilution in water. We must presume that the reason for the hierarchy of inhibition is that there is a differential susceptibility to a single inhibitor or possibly different inhibitors.

Temperature-controlled Meristic Variation in the Salamander *Ambystoma gracile*

The number of meristic parts in fishes (vertebrae, fin rays, scales, etc.) is often susceptible to modification by temperature or other environmental factors to which the developing embryo is exposed. This has been demonstrated experimentally on at least a dozen fish species[1,2]. In reptiles, one experiment[3] showed that the number of scales on a snake could be raised by higher incubation temperature. Serially repeated parts are less variable in amphibians than in fishes, but among the urodeles the number of vertebrae (or of somites) is known to vary intraspecifically among wild populations, and is sometimes used taxonomically. A hereditary basis to the number of trunk segments in *Plethodon cinereus* has been demonstrated by rearing young from different populations under constant conditions[4]. This communication describes the converse experiment, in which urodele eggs from one locality were reared at various temperatures, to determine whether different environments could produce different meristic counts in young having similar genetic background.

Egg masses of the north-western salamander, *Ambystoma gracile* (Baird), were collected by A. L. Hamilton on April 17, 1964, fron Jacobs (Marion) Lake, 7 miles north-north-east of Haney in the lower Fraser River valley of British Columbia. Each egg mass consisted of from 60 to 140 eggs distributed in a clear stiff jelly matrix. Egg masses had been attached to plant stalks a few inches above the mud bottom in 2–5 ft. of standing water, at 3°–4° C. Each batch was probably laid by a single female within the preceding 2 days.

Each egg mass was divided in two, and each half placed in a basket suspended in aerated water maintained at constant temperature and subject to 15 h artificial light. Fig. 1 shows the distribution of halves of three egg masses, *A*, *B* and *C*, at various rearing temperatures. As a guide to the period during which body segmentation is alterable, those eggs from mass *A* which had been placed at 12° C were again divided, and half of them were moved to the 18° C bath 14 days after start of the experiment. At the same time, half those from mass *A* which had been placed at 18° C were moved to the 12° C bath. Resulting mean costal groove counts of these transferred lots (not shown in Fig. 1) were almost identical to the means of those left permanently at the original temperatures, demonstrating that costal groove count is already determined before 2 weeks at either 12° C or 18° C.

After hatching, the larvae were fed pond plankton and brine shrimps. Animals reared at high temperatures were preserved after 75 days. Those at low temperatures were moved to warmer water after several weeks and were preserved after about 200 days. Snout-vent lengths of most larvae were 15–25 mm when preserved.

Total vertebral count is an unsatisfactory taxonomic character in this salamander, as posterior vertebrae are added well after the young are free swimming and feeding. Counts of total vertebrae visible in cleared and alizarin-stained salamanders varied from about 29 at snout-vent length of 14 mm to about 49 at snout-vent length of 30 mm (the latter being a wild 1-year-old specimen). Accordingly, only the trunk segments were investigated. Determination of trunk vertebral count is difficult in young specimens, because the pelvic girdle has as yet no ossified attachment to the vertebral column, and the position of the first haemal arch may be unclear. Fortunately, a high correlation has been shown[5] between the number of trunk vertebrae and the number of costal grooves which mark the myosepta between adjacent muscle segments. In the present experiment enough specimens were prepared in alizarin and potassium hydroxide to establish that trunk vertebrae displayed a pattern of variation similar to that of costal grooves. The latter are most commonly referred to in taxonomic literature, and may be more accurately and conveniently counted in young salamanders.

All those costal grooves were counted which lay behind the posterior margin of the fore-limb and ahead of the anterior margin of the hind-limb, when the limbs were held out perpendicular to the body axis. If more than half a segment width lay ahead of the first counted groove, and more than half a segment width lay behind the last counted groove, the count was increased by a half unit. Costal groove counts were made on both sides of each specimen and averaged. Sample sizes shown in Fig. 1, and used in calculations of probability, refer to the number of specimens, not the number of sides counted.

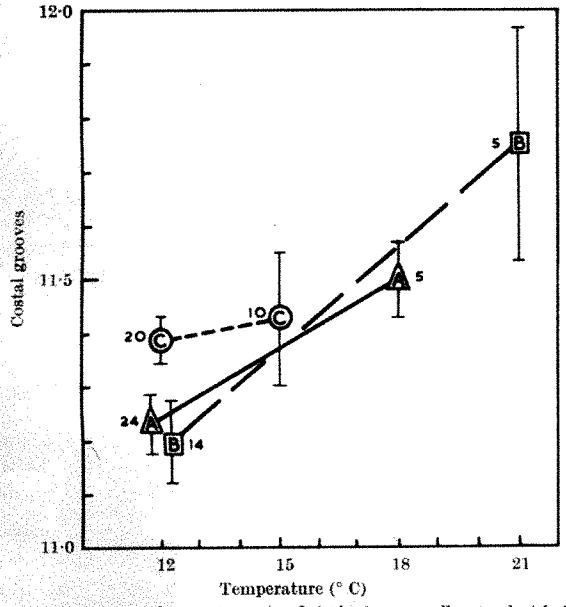

Fig. 1. Mean costal groove counts of *Ambystoma gracile* reared at indicated temperatures. Letters refer to original egg masses. Figures indicate sample size. Vertical bars are ±1 standard error

Individual costal groove counts varied from 10·5 to 13. Combined means were progressively higher at higher rearing temperatures. Within each egg batch, individuals reared at the higher of the two temperatures tested had the higher mean count (Fig. 1). Differences between means for high and low temperature were statistically significant in batches *A* and *B* (*t*-test, $P < 0{\cdot}01$). Also, a significant difference occurred between means from different egg batches reared at the same temperature (between *B* and *C* at 12° C, and also in experiments involving other egg batches not reported here), suggesting genotypic as well as environmentally induced variation.

Because mortalities were in some cases high (20–87 per cent), the possibility that the differences in costal groove count of survivors are due to differential mortality, rather than to phenotypic modification, cannot be dismissed. However, dispersal of counts tended to be high in egg lots with low percentage survival, and low in lots with high survival, which would not be anticipated if temperature were differentially selecting from among a normally distributed assortment of genotypes.

The sub-species *Ambystoma g. gracile* (Baird) used in this experiment is reported to have a modal costal groove count of 10, while the more northerly sub-species *A. g. decorticatum* Cope has 11 or 12 (ref. 6). (The count values given in the literature may not be directly comparable with those given here due to differences in the methods used.) The present demonstration that costal groove number is environmentally labile does not, of course, remove the possibility that there is also a heritable tendency towards higher costal groove counts in the northern sub-species (which displays other, probably genetically determined, differences). However, the likelihood that segmental differences may be phenotypically labile must evidently be borne in mind by urodele taxonomists as well as by fish and reptile taxonomists.

Although environmentally induced changes in meristic series have been documented in many fishes, we are still totally ignorant of their underlying mechanisms. Similar changes can evidently be induced in salamanders. The relative ease of experimental manipulation of urodele eggs[7] (in contrast to teleost eggs) should commend them to experimental embryologists wishing to explore the vexing problems of variability in meristic counts.

[Since preparation of this letter, I have found reported an investigation[8] in which the number of trunk segments of *Triturus vulgaris* was significantly increased by higher rearing temperatures; the number of trunk segments in *Ambystoma mexicanum* was greatest at intermediate temperature with fewer at high and possibly also at low rearing temperatures.]

This investigation was supported by a grant from the National Research Council of Canada.

Sporogenesis in the Bryophyte *Anthocerosis*: Features shown by Fluorescence Microscopy

Fluorescence microscopy has been found useful in bacterial identification, clinical diagnosis, fluorescent antibody techniques, and general cytological studies[1]. Recently, Shellhorn, Hull and Martin[2] have extended the use of fluorescence microscopy to the detection of fresh and fossil pollen grains by using autofluorescence of exines.

In an investigation of sporogenesis in *Anthoceros hawaiensis* Bartlett and related genera, fluorescence microscopy has proved useful in the detection of incipient deposition of the exosporium in the tetrad immediately following meiosis. In preparing the sporogenous tissue for examination, a median bisection of the living sporophyte was placed in distilled water on a glass slide and covered with a No. 1 cover glass. No fluorochrome was added.

The material was illuminated by an incident ultra-violet light from an Osram '*HB*' 200-W mercury lamp with current supplied from a 'Universal' light source, model 250. Observations were made through a Leitz 'Ortho-Lux' microscope. Filters used during the illumination by ultra-violet light were *BG* 38, *BG* 12 and an ocular blue-absorbing filter.

In Fig. 1, two sporocytes are shown as they appear under incandescent illumination. One sporocyte (top) has just formed tetrads, while the one below contains the four chloroplasts which are prominent in the pre-meiotic condition. The same field (Fig. 1 reversed) is shown in Fig. 2, but under ultra-violet illumination. In Fig. 2, the sporocyte containing the tetrad (top) shows the brightly autofluorescing exosporia of the individual spores; this layer shows a greenish-yellow autofluorescent. The exosporium of developing spores and mature spores shows this same greenish-yellow autofluorescence even after the spore is released from the ruptured sporocyte wall. The sporocyte wall itself is not autofluorescent. In the pre-meiotic sporocyte subjected to fluorescence, only the four chloroplasts can be seen because of the red autofluorescence of chlorophyll.

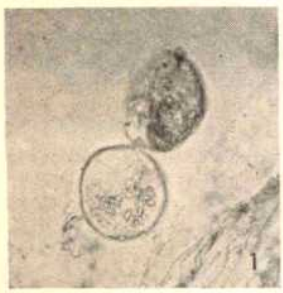

Fig. 1. Two living sporocytes under incandescent illumination. The post-meiotic sporocyte (top) contains a tetrad and the pre-meiotic sporocyte (below) contains four prominent chloroplasts. (× *c.* 770)

Fig. 2. Same field (reversed) as Fig. 1, but under ultra-violet illumination. The strong autofluorescence shows the exosporia of the tetrad in the post-meiotic sporocyte (top); whereas only the four chloroplasts of the pre-meiotic sporocyte (below) show autofluorescence of their chlorophyll. (× *c.* 770)

The phenomenon of autofluorescence in the exosporia of *Anthoceros* suggests that fluorescence microscopy may well be useful in investigations of sporogenesis among other bryophytes. Similar observations of other species of the same genus and representatives of other orders of bryophytes were made. Autofluoresence within the exosporium was found in the following species: *Reboulia hemisphaerica*, *Fossombronia salina Lindb*, *Anthoceros laevis* L., and *Anthoceros punctatus* L. With this technique, distinct developmental changes can easily be observed between the pre-meiotic and post-meiotic conditions. Indeed, fluorescence microscopy may also prove useful in studying exine development in angiospermous species. Exines of *Yucca treculeana* also exhibit bright yellow-green autofluorescence. The similarity of autofluorescence in bryophyte exosporia and pollen exines suggests a homologous chemical composition.

MICROBIOLOGY

Transformation by Hybrid DNA in *Bacillus subtilis*

Doty *et al.*[1] have reported that when an aqueous solution of DNA is heat-denatured and then annealed by slow cooling, the complementary strands separated by the thermal treatment recombine specifically. By this method, Marmur and Lane[2] made hybrid DNA molecules in which one of the complementary strands derived from the DNA of a streptomycin-resistant strain of *D. pneumoniae*, and the other strand from a wild-type strain. The hybrid molecules thus formed were said to be functional in transforming *D. pneumoniae* to streptomycin resistance.

In certain transformation experiments Herriott[3] used a molecular hybrid of the DNA extracted separately from two strains of *Hemophilus influenzae*, one streptomycin-resistant and the other catomycin-resistant. He found the number of double transformants to be significantly higher (fifty-fold) than with the control—a mixture of the two DNA materials denatured and renatured separately. This result may suggest that both strands of the hybrid molecule are effective in expressing the information into the recipient cell. Different results were obtained by Marmur *et al.*[4] and by Kent *et al.*[5] in *D. pneumoniae*.

Recently, Bresler *et al.*[6] obtained results for *B. subtilis* similar to those of Herriott. Using *his*$^-$ and *try*$^-$ strains as DNA donors, they observed that the hybrid DNA can transform a double auxotrophic strain to a prototrophic one. Moreover, when DNA synthesis by recipient cells is excluded, the hybrid molecules are still able to stimulate the ability of double auxotrophic cells to synthesize histidine and tryptophan. Therefore they assume that both strands of the double helix can serve as templates for messenger RNA synthesis.

We report here some experiments on transformation by hybrid DNA in *B. subtilis* in the system used by Bresler *et al.* The recipient strain was *B. subtilis SB* 25 ($his^-_2try^-_2$)—a double auxotroph for two linked markers[7,8]. In our experimental conditions, a 'cotransfer index' of 0·5 ± 0·03 was calculated. The two donor DNAs were isolated by Marmur's method[9]—one from a *B. subtilis* strain auxotrophic for histidine only (*SB* 25 his^-_2) and the second from a strain requiring tryptophan (*SB* 25 try^-_2). Hybrid DNA was formed by the procedure of Schildkraut *et al.*[10]. (For more details see the legend to Table 1.) In transformation assays the methods of Spizizen[11] and Nester *et al.*[8] were both used successfully. The most reliable results were obtained by a slight modification of the latter (20 μg/ml. of L-histidine in CHT 2 and CHT 10 media).

Table 1 shows that the number of double transformants obtained with the hybrid DNA is significantly higher than with the control mixture. A ratio his^+try^+/his^+ of 1×10^{-2} may be calculated. This value is close to that found by Bresler *et al.* in the same system.

We also undertook some experiments to test the hypothesis that the hybrid DNA is integrated into the host genoma and the markers carried by each strand are both expressed in the recipient cell. The inclusion of a hybrid molecule into the host DNA is only one of the conditions necessary for the formation of double transformants. There must be a subsequent semi-conservative duplication of bacterial DNA which results in two double helices each having only one active genetic marker. To reconstitute the wild-type genotype a crossing-over between *his*⁻ and *try*⁻ loci must occur during the first cellular division. This event is expected to be very rare since *his*⁻ and *try*⁻ loci are closely linked.

Table 1. TRANSFORMATION BY HYBRID DNA COMPARED WITH THAT OF THE CONTROL MIXTURE

Experiment	DNA samples	μg/ml.	Recipient cells/ml. ($his^-try^-_2$)	Number of transformants/ml. $his^+try^+_2$	$his^-try^+_2$	$his^+try^+_2$
1	Control mixture	4	4×10^8	7×10^3	3×10^5	23
	Hybrid mixture	4	4×10^8	$1{\cdot}8 \times 10^4$	3×10^5	190
2	Control mixture	4	4×10^8	7×10^3	3×10^5	20
	Hybrid mixture	4	4×10^8	$1{\cdot}8 \times 10^4$	3×10^5	105

Hybridization procedure: 10 μg of DNA from his^-_2 strain and 10 μg of DNA from try^-_2 strain in 1 ml. of solution containing sodium chloride 0·3 M and sodium citrate 0·03 M were heated at 100° for 10 min. The tube was quickly transferred to a bath held at 67° C. After 2 h the DNA solutions were allowed to cool to room temperature.

Transformation assay: 0·2 ml. of hybrid DNA were added to 0·9 ml. of competent bacteria (*SB* 25 his^-try^-). As a control 0·2 ml. of a mixture of both DNAs, denatured and renatured separately, were added to 0·9 ml. of competent bacteria. The tubes were incubated at 37° C for 30 min with gentle shaking. Diluted samples were plated on minimal agar plates containing 40 μg/ml. of *l*-histidine or 20 μg/ml. of *l*-tryptophan. To score double transformants 1 ml. undiluted sample was plated on minimal agar.

Table 2. CLONAL ANALYSIS OF TRANSFORMED CLONES

Exp.	Total No. of clones examined	Pure clones + −	+ +	Mixed clones + − and + +
1	69	32	36	1
2	164	75	88	1

Exp. 1: A hybrid mixture of the DNA from a prototroph strain with the DNA from try^-_2 strain was used in transforming the competent cells of *SB* 25 his^-try^-. Transformed clones were picked up from a tryptophan-agar plate and streaked on complete medium in order to get about 100 separated colonies. The plates were replicated on minimal medium and minimal medium plus tryptophan.

Exp. 2: A hybrid mixture of the DNA from a prototroph strain with the DNA from his^-_2 strain was used in transforming the competent cells of *SB* 25 his^-try^-. Transformed clones were picked up from a histidine-agar plate and streaked on complete medium in order to obtain about 100 separated colonies. The plates were replicated on minimal medium and minimal medium plus histidine.

The symbol + − stands for a cell transformed for only one marker, + + for a cell transformed for both markers.

The segregation of the markers should be much more frequent. In this case a genetic analysis of the transformed clones should detect a large number of mixed clones, theoretically twice the number of single transformants. To test this possibility, a mixture of the DNA from a prototroph strain with the DNA from a single auxotroph strain (*SB* 25 his^-_2 or try^-_2) was used. *SB* 25 $his^-_2try^-_2$ was transformed with these hybridized DNAs and plated on minimal media supplemented with L-histidine or L-tryptophan, respectively. The clonal analysis of transformed cells (Table 2) shows the extremely low number of mixed clones compared with the other classes of transformants.

We were not able fully to evaluate this result without a previous quantitative control of the hybrid DNA formation. However, our data suggest that only one strand of the hybrid molecule is active in expressing the information into the recipient cell. The experiment of Lacks[12] on the fate of transforming DNA soon after penetration in the *D. pneumoniae* cell, and the results of Fox and Allen[13] on the mechanism of DNA integration in pneumococcal transformation, lend support to this hypothesis. Experiments are in progress in which one of the two donor DNAs is density labelled with deuterium and nitrogen-15, and in which denaturation and renaturation of the mixture are followed in a caesium chloride gradient.

ENTOMOLOGY

Resistance to a Chemosterilant, Metepa, in *Aedes aegypti* Mosquitoes

THE spectacular eradication of the screw-worm fly *Callitroga hominovorax* (Coquerel) through the release of male flies sexually sterilized by γ-irradiation has stimulated efforts to combat other insect populations by sexual sterilization[1,2]. Sterilization by γ-irradiation has the disadvantages that it may reduce sexual aggressiveness of males, that huge numbers of insects must be laboratory reared for release subsequent to sterilization by the stationary source of radiation, and that the behaviour patterns of laboratory adapted strains may have become altered from those of wild populations[3].

To circumvent these difficulties, intensive efforts have been made to discover chemicals which might be used to sterilize insects in the field[4]; and a number of candidate chemosterilants have been found such as tepa (*tris* (1-aziridinyl) phosphine oxide), metepa (1,2 *tris* [1-(2-methylaziridinyl)] phosphine oxide), and apholate (2,2,4,4,-6,6,-hexa (1-aziridinyl)-2,4,6-phosphine oxide). However, as in the case of insecticides the reduction of the number of insects by means of chemicals may result in the development of resistance to them by Darwinian selection for pre-adaptations[5]. In order to avoid control failures it is advantageous to know whether resistance to a chemical will develop, how quickly and to what magnitude. High insecticide-resistances are usually determined by a single gene-allele for a powerful detoxifying enzyme[6–8]. Such resistances can be directly combated by finding an inhibitor for the detoxifying enzyme[7,8], or by modifying the molecular structure of the chemical to fall outside the range of the enzyme's substrate specificity[9].

Such an incipient resistance to one chemosterilant, aphoxide, has recently been reported in *Aedes aegypti* (Linn.)[10]. This communication reports the outcome of the artificial selection with metepa in *Aedes aegypti*, and furthermore indicates the physiological mechanism of this resistance.

A susceptible laboratory strain of *Aedes aegypti* supplied by Dr. G. B. Craig, University of Notre Dame, was used for this investigation. Larvae were reared at a density of 100–150 in white enamel pans 10 × 12 in. with deep water and fed daily on a coarsely ground mixture of equal parts of 'Kellogg's Concentrate', wheat germ and live yeast. This rearing method provided vigorous larvae of uniform size. The adults were maintained in screened cages 12 × 12 × 12 in. in an insectary maintained at

80° F and 80 per cent relative humidity, and were fed on guinea-pigs and honey. Oviposition was accomplished in a water-filled fingerbowl lined with filter paper. These papers on which the eggs had been laid were hung within the insectary for at least 72 h for conditioning prior to hatching the eggs in deoxygenated water.

Selection for resistance was carried out by exposing large numbers of early fourth instar larvae to the metepa solution until pupation. Adults, without being selected further, were placed in a cage and maintained for egg production. Lots of approximately 50–100 larvae were placed in 250 ml. water at 22° C to which 1 ml. ethanolic solution of metepa was added. The first two generations were selected with 16 p.p.m., the third, fourth and fifth with 32 p.p.m. and the sixth, seventh and eighth with 64 p.p.m.

The principal mode of action of tepa seems to arise from its ability to reduce the egg hatchability through male sterilization[11]. In order to determine the levels of egg hatchability, 200 larvae were exposed to each concentration required. This was done by exposing fifty larvae in a glass jar containing 250 ml. water at 22° C to which 1 ml. ethanolic solution of metepa was added. Eggs from these exposed mosquitoes were conditioned as already described, and the percentage hatch was determined by using 200 eggs per concentration. The whole experiment was repeated with entirely different batches of eggs in order to ensure the constancy of the data.

The parental strain produces a preponderance of non-embryonated eggs, and this is evident in Fig. 1. Selection with metepa for eight generations produced a strain which laid only viable eggs. It is also evident from the figure that the F_8 generation had developed a low measure of resistance.

An attempt was also made to elucidate the biochemical mechanism of metepa-resistance in the resistant F_8 individuals. To 1 ml. of the larval homogenate, containing 20 mg wet weight of larval material per 1 ml. in phosphate buffer at *p*H 7·4, 0·01–0·1 ml. 10 per cent metepa solution in acetone was added. The system in a test-tube was incubated with gentle shaking for 30 min at 30° C. The reaction was stopped by transferring the test-tube into an ice-acetone bath. Unreacted metepa was then extracted with 3 ml. of chloroform and dried over sodium sulphate. After re-extracting the aqueous phase and sodium sulphate with an additional 6 ml. fresh chloroform and readjusting the combined total volume to 10 ml. in a volumetric flask, 0·1 ml. of the final chloroform solution was transferred to another test-tube. The solvent was removed by means of a stream of dry nitrogen, and the phosphorus content of the remainder was assessed by microchemical analysis[12]. Standard samples with known amounts of metepa in the homogenate, as well as the colour controls, were used to determine the actual amount of metepa in those preparations. The remaining samples were also tested by means of paper chromatography[13] to ensure the purity of metepa in the chloroform solution. The result of six independent determinations of metepa breakdown at 1 mg/ml. of substrate concentration indicated that the resistant homogenate had almost three times as much breakdown capacity of metepa as the susceptible one, the breakdown rate being 37·5 ± 1·9 and 12·9 ± 3·6 μg/mg tissue/30 min respectively. The *t*-value between these two sets of data becomes 6·03, and, therefore, the interstrain difference may be considered as a statistically significant one. The rate of breakdown in both the homogenates, however, did not increase beyond these values when the substrate concentration was raised from 1 mg/ml. to 10 mg/ml. This could mean either (1) the enzyme system is saturated at 1 mg/ml., or (2) there could be active absorption or conjugation to eliminate the limited amount of substrate from the solution in both homogenates. In either case the resistant homogenates have a more efficient method of eliminating metepa at lower substrate levels; however, at high levels this inter-strain difference becomes less effective.

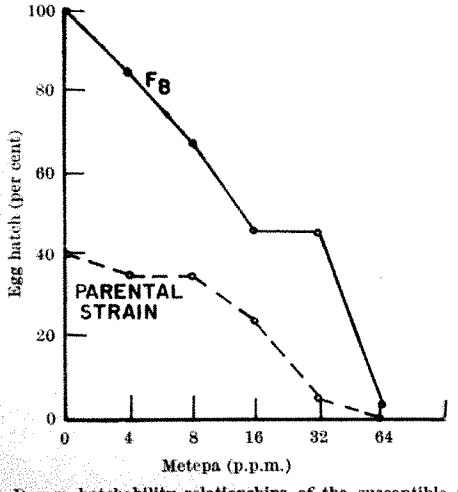

Fig. 1. Dosage–hatchability relationships of the susceptible parental and resistant F_8 strain eggs

Insect populations may respond to selection with every potentiality for resistance that is present within their gene pool. This strain seems to have responded (1) by laying only viable eggs, and (2) by developing an enzymatic degradation system and/or active elimination system for metepa in the body. The former factor seems to play a relatively important part, but the latter factor could also become very important where the selection pressure is very severe and the need of an efficient detoxication system becomes very critical. Our investigation indicates that a population of *Aedes aegypti* may respond to metepa and develop resistance within a few generations when treated at the larval stages. This does not exclude the possibility that field trials with other means of application would produce results entirely different from ours. Nevertheless, as a rule more genes and their combinatory probabilities are available in field populations than in laboratory colonies, and so caution should be applied when carrying out the field control programme, otherwise formidable resistance problems may have to be faced in the future.

We thank Prof. J. B. Kitzmiller for the use of his insectary and laboratory space. This investigation was in part supported by grants from Hatch Project 822 on Biologically Active Substances and from the U.S. Public Health Service, National Institutes of Health (grant *ES*–00067 and *E*–3486).

VIROLOGY

Isolation of a Poxvirus from Stock Type 12 Adenovirus

Sweet and Hilleman[1] detected *SV40* in seed stocks of adenoviruses, types 1–7, and Gerber *et al.*[2] reported the presence of viable *SV40* in formalinized adenovirus vaccines. Yang and Melnick[3] described *SV40* contamination of both adenovirus stock and vaccine. Such contaminations were attributed to the *SV40* flora in many of the 'normal' monkey kidney cell cultures used for propagation of adenovirus. The report presented here describes the isolation of a poxvirus contaminant from a seed stock of adenovirus type 12. The poxvirus had been propagated by us in undetected form through many passages of the adenovirus in *HEp*-2 cells.

HEp-2 cell cultures, inoculated with stock adenovirus type 12, developed a cytopathogenic effect which was characterized by rounded and clumped cells and well-defined intranuclear inclusion bodies. Monkey kidney cell cultures, inoculated with the same undiluted adenovirus stock, developed a severe toxic reaction with marked cytopathogenic effect and intranuclear inclusion bodies; however, comparatively little infectious virus was produced. When the monkey kidney cell cultures were inoculated with the adenovirus diluted 1 : 10, plaques appeared in the cell sheet which resembled those of poxvirus. DNA-staining cytoplasmic inclusion bodies were observed by acridine orange fluorescence microscopy which were characteristic of those found in poxvirus-infected cells. In monkey kidney cell cultures inoculated with two-fold dilutions of the adenovirus stock (0·1 c.c.), the pox-like plaques appeared when the stock was diluted 1 : 4 or higher. The concentration of the poxvirus was $1{\cdot}6 \times 10^2$ plaque-forming units (P.F.U.) per ml. of adenovirus stock. The contaminating poxvirus (designated *TC*17) was detected in adenovirus stocks prepared on prior occasions from the same virus seed, as well as in the original vial of virus stock which was received from the custodian of the prototype virus. By diluting the adenovirus beyond its end-point in cultures of monkey kidney cells, the poxvirus contaminant was recovered free of adenovirus; and a pool of stock virus was prepared from this for further investigation.

When monolayers of *HEp*-2 cells were inoculated with *TC*17 virus, free of the adenovirus, plaques appeared and infectious virus was produced; however, the plaques appeared more slowly and were smaller and less easily detected than those produced in monolayers of monkey kidney cells. DNA-staining cytoplasmic inclusions were also observed in *HEp*-2 cells infected with *TC*17 virus and examined by acridine orange fluorescence microscopy.

Opaque white pocks were induced by *TC*17 on the chorioallantoic membrane of embryonated eggs. The surface of the pocks often appeared umbilicated. Three-week-old Swiss–Webster mice resisted intracerebral inoculation of 10^3 P.F.U. of *TC*17 virus; however, six of eight mice inoculated intracerebrally with 10^5 P.F.U. died 3 days after inoculation. Neither lesions nor symptoms were observed in mice inoculated intraperitoneally or intradermally with the virus. Rabbits developed a localized papule 2–3 days after intradermal inoculation of the poxvirus, and the lesions evolved through vesicle and pustule stages and were crusted over in 8–9 days.

While diethyl ether had no effect on the virus, it was inactivated by chloroform. Antiserum prepared against *TC*17 virus neutralized both vaccinia and monkeypox viruses, members of the same sub-group of poxviruses[4]. Rectangular or brick-shaped elementary bodies typical of poxviruses, were observed in the cytoplasm of infected cells by electron microscopy.

The biological and physical properties of the contaminating *TC*17 virus identify it with the poxvirus group; and, in view of its close serological relationship to vaccinia and monkeypox, it can be placed in the vaccinia-variola sub-group of poxviruses. This includes the viruses of monkeypox, ectromelia, cowpox, and contagious pustular dermatitis[4].

The discovery of poxvirus in the original stock of adenovirus type 12 and its inapparent but persistent propagations along with adenovirus in *HEp*-2 cells suggests the existence of an interference mechanism. Pereira[6] showed that adenovirus-infected HeLa cells produced a factor which inhibited multiplication of vaccinia virus in HeLa cells. Recent studies of Khoobyarian[7] have indicated that, under certain experimental conditions, the interaction of adenovirus with *RHF*-1 cells would result in cell resistance to vaccinia virus. It is conceivable that some similar mechanism, aided by the low concentration of the poxvirus, permitted it to exist undetected in the adenovirus stock. It is possible that a double infection resulting from the use of contaminated stocks could result in suppression of one, or its survival as an inapparent infection. The second virus would remain hidden until the conditions of propagation were changed in its favour. This may explain the emergence of poxvirus in monkey kidney cells.

The contaminating poxvirus may have originated from an occult infection in an earlier cell culture in which the adenovirus had been propagated or it may have resulted from a laboratory contamination prior to receipt in this laboratory.

GENETICS

New Method of Isolating the Tetrads of Agarics

HITHERTO the usual technique for isolating tetrads from Agarics has been to detach a piece of gill tissue from a mature sporophore and then, with the aid of a micromanipulator, to pick off whole tetrads directly from the fresh gill. There are three main difficulties inherent in this method: (*a*) because of the high numerical density of tetrads on the gill, it is very difficult to be sure that no extraneous spores have been picked up by the micromanipulator needle until the spores are parked on the germination medium; (*b*) it is impossible to distinguish unripe from ripe tetrads, and since the former are removed from their basidia with great difficulty, many abortive attempts to pick up tetrads are frequently made before a tetrad is successfully removed; (*c*) in the case of *Coprinus*, autolysis of the gill can greatly limit the time available for isolation.

In the course of analysing tetrads from *Coprinus lagopus* (for the purpose of finding new centromere markers to be used for the extension of mapping) a new method has been developed. If a piece of gill tissue is taken from a mature sporophore, placed on a microscope slide and allowed to dry, the spores can be scattered on to the surrounding glass by sweeping the micromanipulator needle across the dried gill. Among the spores on the glass there is nearly always a high proportion of whole tetrads (Fig. 1), and these can very easily be removed from the

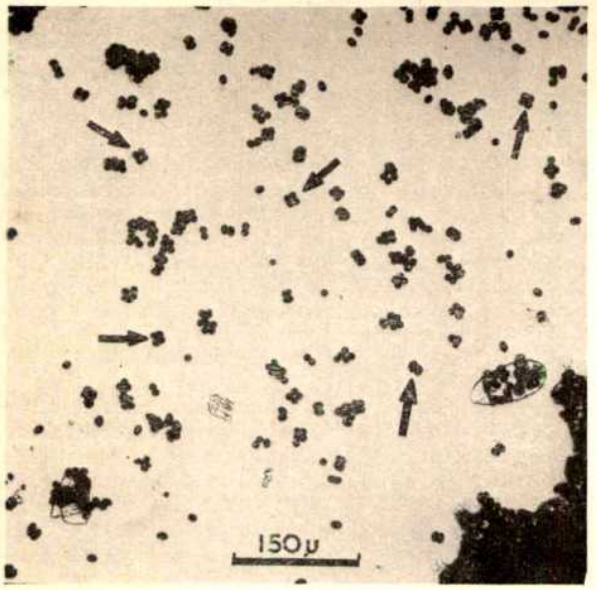

Fig. 1. Photomicrograph of spores scattered from dried gill. There are more than twenty tetrads in this field which are available for picking-off; five of them are arrowed as examples

glass. Drying may be hastened by placing the slide carrying the gill into a Petri dish containing a layer of dry silica gel.

During drying the four spores of each tetrad become aggregated into a single mass so that, when drying is complete, each tetrad tends to behave as a single unit. This presumably accounts for their easy removal as whole tetrads by this somewhat drastic method.

The great advantage of this 'on-glass' technique is that whole tetrads can be stored as such for long periods: in one case tetrads isolated four months after scattering still gave 85 per cent germination. Thus many tetrads can be isolated over a comparatively long period of time as and when it is convenient to do so, with the advantage that all originate from the same fruiting body. Slides carrying scattered spores are best stored over silica gel at room temperature.

That the on-glass technique still provides a random sample of tetrads was demonstrated by a cross in which 104 tetrads were isolated from fresh gill using the old method, and a further 49 isolated from glass. Both sets of data were completely homogeneous.

I thank Prof. N. F. Robertson for providing facilities, and both he and Dr. D. H. Morgan for their continued help and encouragement. This work was performed during the tenure of a D.S.I.R. research studentship.

AGRICULTURE

Carbon- and Nitrogen-levels of a Medium in Relation to Growth and Nematophagous Activity of *Arthrobotrys oligospora* Fresenius

During the past few years, attempts have been made to enhance the nematode-trapping activity of nematophagous fungi in the soil by adding various carbohydrates[1,2]. As a preliminary investigation to similar experiments, we cultured *Arthrobotrys oligospora* and measured its growth and nematophagous activity on semi-synthetic media having different levels of carbon and nitrogen.

The basic medium had the following ingredients: dipotassium phosphate, 1·0 g; magnesium sulphate, 0·5 g; potassium chloride, 0·5 g; ferrous sulphate, 0·01 g; yeast extract, 3·0 g; agar, 15·0 g; and distilled water to make 1 l. of medium. Dextrose and ammonium nitrate were added to this medium at the rates shown in Table 1. Eight replicate Petri dishes of each medium were inoculated with a culture of *A. oligospora*, which had been growing on Lima bean agar.

After 2 days of incubation at room temperature, the fungal colonies were about 40 mm in diameter. A standard number of free-living nematodes (*Rhabditis* (*Cephaloboides*) *oxycerca* de Man. 1895), which had been surface sterilized in a 1 : 10,000 solution of mercuric chloride and washed thoroughly with sterile water, was then added to each of four of the original eight replicate cultures on each medium. The nematodes were allowed to be trapped for 1 week. The remaining four replicate cultures on each medium were grown for an additional 3 days, after which the diameters of the fungal colonies were measured.

The effect of the levels of dextrose and of ammonium nitrate of the medium on the nematode-trapping activity of *A. oligospora* was determined by transferring the contents of the plates to Baermann funnels and counting the extracted nematodes the next day. The number of nematodes recovered is assumed to be inversely proportional to the number trapped by the fungus.

Table 1. Effect of Carbon- and Nitrogen-levels on Growth and Nematophagous Activity of *Arthrobotrys oligospora*

Carbon- and nitrogen-levels (mg/l.)		Diameter of colony (mm)		Nematodes recovered	
Dextrose	Ammonium nitrate	Mean*	S.D.	Mean†	S.D.
50	5	80	2·6	630	41·3
100	10	78	1·8	711	88·7
200	20	81	0·3	197	64·6
400	40	72	0·2	177	18·9

* Mean of four colony diameters.
† Mean of six counts.

Media low in dextrose and ammonium nitrate supported less nematophagous activity of *A. oligospora* than media containing higher concentrations of these compounds (Table 1). As there was little difference in the amount of radial growth made by the fungus on these media, the effect of the carbon- and nitrogen-levels is assumed to have been on its nematode-trapping activity. The sharp decline in nematophagous activity at a level of dextrose and of ammonium nitrate between 100–200 and 10–20 mg/l., respectively, suggests the existence of a critical point or range in nutritional levels which determines a saprophytic or parasitic mode of existence for the fungus.

These observations cast some doubt on the validity of Duddington's[3] suggestion that nematophagous fungi may be most actively parasitic when grown on media of low nutritional value. Rather, these findings support Cooke's[2] view that nematode-trapping fungi need an organic energy source, other than nematodes, in order to remain in an active nematophagous state. The results of unpublished greenhouse investigations[4] indicate that small quantities of dextrose and ammonium nitrate added to soil enhance the nematode-trapping activity of *A. oligospora*.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, March 14

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. A. Waldron: "The Explanation of Some Fundamental Phenomena of Modern Physics using a Ballistic Theory of Light".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. G. S. C. Brown "The Ten-Element Band-Pass Filter Section and Its Applications".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Sky Above, the Mud Below" (colour film).

Monday, March 14—Friday, March 18

OIL AND COLOUR CHEMISTS' ASSOCIATION (in the Great Hall of Alexandra Palace, London, N.22)—Eighteenth Technical Exhibition.*

Tuesday, March 15

UNIVERSITY OF LONDON (at the London School of Economics and Political Science, Houghton Street, London, W.C 2), at 5 p.m.—Prof. L. W. Martin "Problems of Nuclear Strategy" (further lecture on March 17).*

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (in Lecture Theatre No. 2, Physics Department, Imperial College, London, S.W.7), at 5.30 p.m —Prof. J. C. Shepherdson. "Can Mathematical Proof be Mechanized?"

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. J. C. Anderson "The Science of Materials" (Inaugural Lecture).*

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. C. G. Bernhard (Stockholm). "The Corneal Surface Formation of the Compound Eye and Its Function".*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31-34 Gordon Square, London, W.C.1), at 5.45 p.m.—Mr. J. Mellaart: "Excavations at Catal Huyuk, 1965".*

Tuesday, March 15—Wednesday, March 16

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1)—Symposium on "The Planning of Mechanical Engineering Departments in Universities and Colleges of Technology".

PLASTICS INSTITUTE (at the Institution of Electrical Engineers, Savoy Place, London, W.C 2)—Conference on "Flame Resistant Polymers".

Wednesday, March 16

BRITISH POSTGRADUATE MEDICAL FEDERATION, UNIVERSITY OF LONDON (at the Institute of Dental Surgery, Eastman Dental Hospital, Gray's Inn Road, London, W.C.1), at 5.30 p.m.—Prof. D. Slome: "Physiology of Swallowing". (Last of three lectures on "The Scientific Basis of Dentistry".)*

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. T. Gooding. "Cable Fault Localization on Power Systems".

INSTITUTE OF INFORMATION SCIENTISTS (at The Whitehall Hotel, Bloomsbury Square, London, W.C.1), at 6.15 p.m.—Mr. L. Gordon: *"The Economist* Intelligence Unit".

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Manson Theatre, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C 1), at 6 30 p.m.—Discussion Meeting on "Technician Training".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Overseas League, Park Place, London, S.W.1), at 6.30 p.m.—Mr. D. Munday. "Costing".

SOCIETY FOR ANALYTICAL CHEMISTRY, MICROCHEMICAL METHODS GROUP (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion Meeting on "The Determination of Molecular Weights".

Thursday, March 17

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Meeting for the Election of Fellows. 4.30 p m.—Prof. F. Sondheimer "The Annulenes" (Review Lecture).

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. B. C. Sharman, Miss H. P. Aziz and Miss J. C. Miller. "Developmental Morphology and Anatomy of the Shoot in Cereals, with special reference to Wheat (*Triticum*)".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. H. P. F. Swinnerton-Dyer: "Zeta Functions and Algebraic Geometry".

UNIVERSITY OF LONDON (at Goldsmiths' College, New Cross, London, S E.14), at 5 p m.—Prof R. J. Blin-Stoyle: "The Physical Sciences Today".*

UNIVERSITY OF LONDON (at Westminster Medical School, Horseferry Road, London, S.W.1), at 5.15 p.m.—Dr. D. G. Gibson: "Sodium Excretion in Chronic Renal Failure".*

INSTITUTE OF PETROLEUM, ECONOMICS AND OPERATIONS GROUP (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. Christopher Tugendhat: "Co-ordinating Energy Policy".

CHEMICAL SOCIETY (in the Large Physics Theatre, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Prof. R. M. Barrer, F.R.S. "Some Chemical Aspects of Mineral Synthesis" (Hugo Muller Lecture).

INSTITUTE OF REFRIGERATION (at Lloyds' Register of Shipping, 71 Fenchurch Street, London, E.C.3), at 6 p.m.—Informal Discussion on "Education and Training for Refrigeration Technicians".

INSTITUTION OF MECHANICAL ENGINEERS, NUCLEAR ENERGY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Reactor Maintenance and Inspection".

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (at 17 Bloomsbury Square, London, W.C.1), at 6 p.m.—Mr. D. A. Cahal: "The Assessment of Safety of Drugs".

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at the Royal Army Medical College, Millbank, London, S.W.1), at 7.30 p.m.—Laboratory Meeting.

Friday, March 18

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 10 a.m.—Dr. D. Burkitt (Makerere): "Recent Developments in Aetiology and Treatment of African Lymphoma".*

INSTITUTE OF NAVIGATION (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 5.30 p.m.—Mr. C. R. Ditchfield: "Microwave Radiometry".

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.7), at 7 p.m.—Conversazione.

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. R. L. F. Boyd: "Mission to Mars".

Saturday, March 19

BRITISH INSTITUTE OF RADIOLOGY (at the Middlesex Hospital Medical School, Cleveland Street, London, W 1), at 10 a.m.—Symposium on "Radioisotopes in the Hospital—Applications in Clinical Investigation and Diagnosis".

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr Audrey Butt. "Shamanism—The Techniques and Function of Spirit Contact".*

Monday, March 21

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Discussion Meeting on "Isolation, Identification and Estimation of Organophosphorus Pesticides Residues".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 6 p m.—Mr. H. N. G. King: "Electron Beam Welding and Machining".

INSTITUTION OF MECHANICAL ENGINEERS, APPLIED MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Brittle Fracture".

SOCIETY FOR VISITING SCIENTISTS (at the English-Speaking Union, Dartmouth House, 37 Charles Street, London, W.1), at 7 30 p m.—Discussion Meeting on "The Shape of Ships to Come". Chairman: The Right Hon Lord Geddes, C.B.E. Speakers: Mr. A. Silverleaf, Mr C. S. Cockerell and Sir William Lithgow.

Monday, March 21—Tuesday, March 22

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2)—Symposium on "Light Sources".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

LECTURER (Grade II) IN PURE MATHEMATICS—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (March 14).

ASSISTANT LECTURER (with interests in sedimentology or palaeoecology) IN THE DEPARTMENT OF GEOLOGY—The Secretary, The University, Edinburgh (March 16).

LECTURER IN MECHANICAL ENGINEERING IN THE THERMODYNAMICS AND FLUID MECHANICS DIVISION OF THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, Manchester College of Science and Technology, Sackville Street, Manchester, 1 (March 19).

RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICS for research on aspects of far infra-red instrumentation—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (March 19).

LECTURER or ASSISTANT LECTURER (with a good honours degree in electrical engineering or an honours diploma in technology) IN THE DEPARTMENT OF ELECTRICAL AND ELECTRONIC ENGINEERING—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1, quoting Ref. EED (March 21).

POSTDOCTORAL RESEARCH FELLOW (preferably with some familiarity with solid state theory) IN THE DEPARTMENT OF APPLIED MATHEMATICS AND MATHEMATICAL PHYSICS, to work on the theory of semiconductor lasers and to establish contact with government research establishments working in this area—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff, South Wales (March 21).

ASSISTANT IN RESEARCH (with an honours degree in engineering or an appropriate science, or a postgraduate qualification in agricultural engineering or farm mechanization) IN AGRICULTURAL ENGINEERING—The Secretary, School of Agriculture, University of Cambridge, Downing Street, Cambridge (March 23).

ASSISTANT LECTURER or LECTURER (competent to teach genetics at the undergraduate and postgraduate levels although research interests may be in some other field) IN ZOOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (March 25).

ASSISTANT LECTURER or LECTURER (preferably with a special interest in one of the following fields: genetics, biochemistry, developmental biology and experimental morphology, embryology, mycology, entomology and experimental animal ecology) IN THE DEPARTMENT OF BIOLOGY—The Secretary, University of Lancaster, Bailrigg House, Lancaster (March 26).

LECTURER IN RADIOLOGY (joint appointment with the Northern Ireland Hospitals Authority)—The Secretary, The Queen's University, Belfast, Northern Ireland (March 26).

LECTURER or ASSISTANT LECTURER (with postgraduate experience in genetics and biometry) IN AGRICULTURAL BOTANY—The Registrar, University College of Wales, Aberystwyth (March 26).

JUNIOR RESEARCH FELLOW IN BIOLOGICAL SCIENCE, or related subjects—The Secretary, Balliol College, Oxford (March 28).

LECTURER IN GEOPHYSICS IN THE DEPARTMENT OF EARTH SCIENCES—The Registrar, The University, Leeds, 2 (March 28).

LECTURER IN THE DEPARTMENT OF APPLIED MATHEMATICS AND THEORETICAL PHYSICS—The Secretary of the Appointments Committee of the Faculty of Mathematics, University of Cambridge, Silver Street, Cambridge (March 30).

ASSOCIATE PROFESSOR OF BIOCHEMISTRY—Prof. G. E. Connell, Chairman, Department of Biochemistry, University of Toronto, Toronto 5, Ontario, Canada (March 31).

CHAIR IN STRUCTURAL ENGINEERING IN THE DEPARTMENT OF CIVIL ENGINEERING—The Registrar, Manchester College of Science and Technology, Manchester, 1 (March 31).

LECTURER (Grade II) IN THE DEPARTMENT OF THEORETICAL MECHANICS—The Registrar, University of Bristol, The Senate House, Bristol, 2 (March 31).

LECTURER (with special qualifications in the teaching of educational sociology, and preferably teaching experience in other subjects) IN EDUCATION—The Registrar, King's College (University of London), Strand, London, W C.2 (March 31).

RESEARCH ASSISTANT (with a degree or equivalent qualification in physics or applied science, and preferably experience in practical electronics) IN COSMIC RAY PHYSICS, to join a small group working on an experiment to detect cosmic ray neutrinos deep in the gold mines of Southern India—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (March 31).

UNIVERSITY LECTURER and a UNIVERSITY DEMONSTRATOR IN THE DEPARTMENT OF ANIMAL PATHOLOGY IN THE SCHOOL OF VETERINARY MEDICINE—T. D. Kellaway, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge (March 31).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS (normally below the age of 30, and preferably with a Ph.D. or equivalent research experience) IN BIOCHEMISTRY, CHEMISTRY, CHEMOTHERAPY, ENGINEERING, METALLURGY, PHARMACOLOGY or PHYSICS—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 1).

LECTURER (with a degree in geography and good experience in the teaching of geography) IN EDUCATION—The Deputy Secretary, The University, Southampton (April 1).

LECTURER (with a higher degree in biochemistry and some experience in teaching and research in this subject) IN BIOCHEMISTRY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, April 1).

SECOND CHAIR IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY—The Deputy Secretary, The University, Southampton (April 1).

SENIOR LECTURER IN PURE MATHEMATICS—The Registrar, The University, Hull (April 1).

CHAIR OF AGRICULTURAL ENGINEERING—The Registrar, University of Newcastle upon Tyne, 6 Kensington Terrace, Newcastle upon Tyne, 2 (April 2).

ASSISTANT LECTURER or LECTURER (preferably with a particular interest in spectroscopy or reaction kinetics) IN PHYSICAL CHEMISTRY; and an ASSISTANT LECTURER or LECTURER (preferably with a particular interest in stereochemistry or synthetic chemistry) IN ORGANIC CHEMISTRY—The Registrar, University College of Swansea, Singleton Park, Swansea (April 4)

LECTURER or ASSISTANT LECTURER (preferably with qualifications in biogeography, plants or soils) IN THE DEPARTMENT OF GEOGRAPHY, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 5).

LECTURER or ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of North Wales, Bangor, North Wales (April 18).

CHAIR OF ELECTRICAL ENGINEERING; and CHAIR OF MECHANICAL ENGINEERING at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, April 30).

HEAD OF THE BIOLOGY DEPARTMENT—The Headmaster, Latymer Upper School, London, W.6.

HEAD (preferably specialist in botany or zoology) OF THE DEPARTMENT OF BIOLOGICAL SCIENCES—The Registrar, Goldsmith's College (University of London), New Cross, London, S.E.14.

LECTURER or SENIOR LECTURER (with a special interest in applied mathematics) IN MATHEMATICS—The Registrar, Goldsmith's College (University of London), New Cross, London, S.E.14.

LECTURER (with veterinary or biological qualifications) IN EXPERIMENTAL VETERINARY SCIENCE WITH DUTIES AS ANIMAL CURATOR—The Secretary, Postgraduate Medical School, Du Cane Road, London, W.12, quoting Ref. 11/1.

MASTER (with good qualifications in mathematics) TO SHARE THE VI FORM AND UNIVERSITY SCHOLARSHIP TEACHING IN THIS SUBJECT; and a MASTER TO TEACH PHYSICS IN THE MAIN SCHOOL AND IN THE VI FORM—The Head Master, Mill Hill School, London, N.W.7.

POSTDOCTORAL FELLOW IN RADIOFREQUENCY SPECTROSCOPY IN THE DEPARTMENT OF CHEMISTRY, for research in nuclear magnetic double resonance in collaboration with Dr. Edward W. Randall—The Registrar, Queen Mary College (University of London), Mile End Road, London, E 1.

RESEARCH ASSOCIATE (with a good first degree, a diploma in technology or Grad. R.I.C.) IN THE DEPARTMENT OF CHEMISTRY AND BIOLOGY, to investigate the surface properties of active carbons produced by low-temperature coal carbonization processes—The Principal, Nottingham Regional College of Technology, Burton Street, Nottingham.

SENIOR TECHNICIAN and CHIEF TECHNICIAN IN THE DEPARTMENT OF MEDICINE, Royal Veterinary College, for work associated with the clinical and laboratory investigation into conditions affecting farm animals—Prof. F. R. Bell, Royal Veterinary College (University of London), Hawkshead Lane, North Mimms, Hatfield, Herts.

REALISM OR DISENCHANTMENT?

IS science an election issue, or should it be? The British general election, to be decided on March 31, has obliquely raised this question, for the appeal of the Labour Government to the electorate differs from that which the same body of men made eighteen months ago in its almost conspicuous neglect of science. In 1964 the Labour Party made a memorable, and even startling, declaration that it would harness science and technology to the causes of social and industrial change in such a way as to transform the United Kingdom. Now, only a little later, science and technology are mere second cousins—though, to be fair, not quite poor relations—of the familiar and time-worn ingredients of election manifestos. What has gone wrong? Has a mere eighteen months been enough to persuade the politicians that science does not work? Was the last election manifesto just an exercise in public relations? Or is it that elected governments are less able than parties seeking power to give hostages to fortune by identifying in public the mainsprings of change?

It would be a pity if the youthful brashness of the manifesto on which the present British Government was elected had now been entirely replaced by disillusionment. There have been disappointments, especially for the Government and its supporters, but there have been modest successes as well. The new machinery for financing research in universities is working well. Good ideas do not for long go begging for support. There is a comfortable feeling that the Science Research Council, which dispenses the money, and the Council on Scientific Policy, which advises the Minister of Education and Science, is taking prudent thought not merely for next year but for that following as well.

There is a sadder tale to tell of the Government's handling of technology, even if it may not be that tale of indecision and ineptitude which it is easiest to spin. The difficulty is not that the Ministry of Technology has been ineffectual, but that it has been asked to accomplish the impossible. The objective was to use science and technology with open eyes to modernize British industry and to increase enormously the prosperity of the British economy. The trouble is that science and technology are necessary but not sufficient ingredients of such a revolution.

This is why the Ministry of Technology has often seemed more like a home for vested interests than an instrument of government. Compelled as it has been by narrow terms of reference to find technological solutions to pressing problems, the Ministry has rediscovered a number of uncommonly old-fashioned remedies. Thus it justified the decision to support a massive programme of research and development in computers—not necessarily unwise—in language smacking of protection and the Corn Laws. It argued that the prosperity of Britain demands an independent and viable computer industry, when, on the face of things at least, it might have been wiser to use the money for training computer programmers, for buying imported machines, and for supporting research and development in the next great technological leap forward—whatever that may be. Similarly, in its quite proper attempt to awaken the United Kingdom to the importance of technology, the Ministry has often tended to exaggerate the curiously British gulf between science and technology. It has, for example, smiled uncritically on schemes for teaching a kind of engineering in British schools without recognizing that the difficulty of recruiting able men to engineering may spring from too much and not too little specialized instruction.

Elsewhere, the Ministry of Technology has done useful work. In attempting to stimulate innovation in industry by the judicious placing of development contracts with commercial and academic institutions, the Ministry has usefully elaborated a mechanism sketched out by the old Department of Scientific and Industrial Research. It has also found it to be much more difficult than expected sensibly to invest large sums of money in this way. The National Research and Development Corporation has begun to make use of its increased capital, but here, too, progress has been slower than expected. And there has been no sign, so far, that the Ministry has been able to persuade the Government as a whole to discriminate between the sheep and the goats in industry by deliberately giving its custom to the efficient companies. Indeed, now as when the election manifesto of 1964 appeared, there is no good reason to think that such a device could have more than a marginal effect in changing the complicated pattern of industry.

It is not, of course, surprising that achievement should so often have fallen short of expectation. British industry may be less advanced and less enterprising than it could be, but the reasons are not simply technological. The chronic shortage of investment capital frequently limits the growth for new enterprises, for example. Defects of administration and management are often as cramping as a failure fully to exploit the potentialities of modern technology. The lack of a common sense of the excitement of modern technology, and of its potentiality for innovation, induces British industry to aim at over-modest goals. There is no cause for hoping that the policies which the Ministry of Technology has been pursuing, whatever their merits in isolation, could overcome all these impediments to change.

This is why it would be foolish if British politicians were to allow the frustrations of the past few months to bury entirely their once-proud hopes for science and technology. In reality they—and their electors—can only benefit from a more measured view of what science and technology can accomplish in the modern world. A great deal needs to be done if governments everywhere are to make full use of these instruments of change. In Britain, there is a lot of tedious detail to be dealt with. The separation between science and technology in government needs to be looked at again, and ideally eliminated. Education needs more attention, and more money. The Government has to accustom itself to more money, and more imaginative support, for scientific research and technological development. Administrators must be won over. These, and the host of other jobs which must be tackled, will not be completed overnight. Science and technology is not a magic wand, but a part—and an

important part—of the fabric of modern society. It must not be dropped from the election manifestos, but given a sober place in them. In this sense it is a virtue that in Britain the manifestos make less of science and technology in 1966 than they did in 1964.

RATE FOR THE JOB

THE American Institute of Physics is uncommonly well informed about the jobs its members do, and about the salaries they are paid. The latest batch of figures, made public in *Physics Today* for January, will as usual comfort those struggling for a Ph.D. with the knowledge that their efforts (if successful) are likely to add something like 5,000 dollars to an annual salary in industrial research and development. In 1964 the median starting salary for Ph.D. physicists in industry appears to have been 12,600 dollars, compared with 8,800 dollars for those starting with a master's degree and 7,500 dollars straight after graduation. The initial value of a Ph.D. seems to be equivalent to ten years of plodding up the promotion ladder, and this advantage appears to persist throughout a physicist's career. Whatever his length of service, a Ph.D. can expect to earn 4,000 dollars more each year in industrial research in the United States than somebody less qualified. But the same industrial jobs are curiously unprogressive. The median salary of those with a Ph.D. and twenty years experience (in 1964) was a mere 18,200 dollars, or not quite half as much again as the salary paid to raw recruits. To do better than this, a man must move into what the American Institute of Physics calls "management and administration", which brings an extra 6,000 dollars or so a year to those with long experience. By contrast, academic life offers a lower starting salary but faster promotion; after twenty years, the median salary of academics is 16,600 dollars, or roughly 90 per cent of the comparable salary in industry.

The sociology of physics described by these statistics will allow students to know what to expect. The more mercenary young people may even be tempted to let their academic interests be guided by the knowledge that fluid physics and solid-state physics carried the highest salaries in 1964, and that work on fundamental particles was the most impoverished specialty of all except for theoretical physics. But there are other inferences to be made. High starting salaries and slow promotions reflect the competition for young people leaving universities and the comparative rapidity with which their bargaining power diminishes with age. The profession of physics has something in common with professional football, where a man must reckon that his earning power will disappear altogether by forty. This suggests that university departments might deliberately set out to provide their students with the means of moving out of research into administration half-way through an industrial career, possibly by coupling academic instruction with more deliberate training in the techniques of management and administration. Something like a union of the Massachusetts Institute of Technology and the Harvard Business School might be a fruitful innovation. Meanwhile potential immigrants to the United States will note that starting salaries in physics will not maintain a second car except where the other costs of living are exceptionally low. And physicists sticking to their last should not expect to move into the Waldorf-Astoria for what are called the sunset years.

PEACEFUL USES OF ATOMIC ENERGY

Proceedings of the Third International Conference on the Peaceful Uses of Atomic Energy

Held in Geneva, August 31–September 9, 1964. Vol. 1: Progress in Atomic Energy. Pp. xxxii+477. (New York: United Nations, 1965.) 12.50 dollars.

THE record of the first International Conference on the Peaceful Uses of Atomic Energy, 1955, was published in sixteen volumes; the record of the 1958 Conference grew to forty volumes and many who went to Geneva that year felt that a useful limit had, in fact, been exceeded; six years elapsed before the third Conference, held under the presidency of Prof. Emelyanov, and this 1964 meeting was confined almost entirely to nuclear reactor technology, which has nearly grown to manhood in the 25 years since fission was discovered. The record of the conference has shrunk once more to sixteen volumes embracing 750 papers. In addition to reactor technology, review papers were given on the application of radioactive tracer elements and of large radiation sources to the physical and life sciences. These brought the reactor specialists up to date in the wider applications of atomic energy, and the session on fusion research recounted the progress of this "promise of the twenty-first century" since it received its copious baptism in the 1958 Conference.

The first volume of the *Proceedings of the Third International Conference on the Peaceful Uses of Atomic Energy* embraces the opening and closing addresses, economic studies of the world's needs for energy and the extent to which these might be supplied by nuclear power, some papers on nuclear projects which have been handled on an international collaborative basis, a very important group of papers on technical and economic aspects of reactors, and finally an evening lecture delivered by Prof. Seaborg, in which he summarized the Conference.

As the president said in his opening remarks, "The question to-day is not whether nuclear fission can be regarded as a practical source of power, the question to-day is how to extract this energy as cheaply as possible, and increase its importance in the energy balance sheet". We have proved reserves of uranium for several hundreds of years, and if we go on using organic fuels for power generation, the chemical industry will soon be deprived of this most important source of raw material (his countryman, Mendelejeff, also said this very strongly in 1876, but then there was no alternative fuel in sight). How soon the organic fuels will run out cannot accurately be stated, but a century seems to be the upper limit of time. How cheaply nuclear power can be produced on a very large scale is the subject of several papers.

The British and Canadian reactors have been characterized by high capital costs and low fuel costs, the American by lower capital costs and higher fuel costs, so the former have been particularly affected by the upward swing in interest rates in recent years. Capital costs of all reactors have fallen dramatically with increase in unit size. It has also been found possible to up-rate many reactors, and fuel costs have fallen, with the overall result that new British and American reactors are becoming competitive with modern coal stations. Within a year of the end of the Geneva Conference, the commercial form of the *AGR* Reactor offered to the Central Electricity Generating Board for base-load operation gives the appearance of producing electric power more cheaply than could be produced by coal stations built at the pithead to operate about 1970, while even in 1964 the American 600-MW reactor to be built at Oyster Creek also appeared to be—on rather favourable calculations—cheaper than a coal station at that site. It is interesting to read that in the United States "whether nuclear reactor break-through in costs will be permanent depends as much on actions of competing fuels as on improvements

in the nuclear art; costs of fossil fuels have been declining under the impetus of competition". The Canadian costs forecast for the next large heavy-water reactor are based on a very low fuel cost and much cheaper heavy-water, and they appear to rival American costs per unit of electricity generated, but exact comparisons are difficult; as Prof. Seaborg said in his summary, greater efforts towards standardization of the bases for computing nuclear power costs would probably have been welcomed in the Conference. It must also be remembered that computed costs must be related to system performance: thus, the cost of taking a reactor off the system for a few weeks in order to change its fuel in the middle of the high winter peak load would depend on the spare capacity available, and we read that the overall gross margin in the United States was 27 per cent in 1963, far higher than the margin available in Great Britain. Several papers deal with costs overseas, such as in India, but these cannot easily be related directly back to the Canadian or American costs, as the stations are of smaller output though of later date; both types, however, appear to be cheaper than the United Kingdom gas-cooled types.

The generation of reactors using natural or slightly enriched uranium now being planned leads smoothly into the 1980's. By that date the several larger breeder reactors now being designed should be operating and should be yielding realistic estimates of future capital costs and fuel costs; it should also be possible to assess the impact of the whole fuel cycle on costs for advanced converter reactors. Before that date, large quantities of plutonium will have been made and decisions will be required about its processing. The Canadian authors suggest that as the uranium-oxide cost is not a very important component of the cost of electricity, particularly in the kind of reactor developed in Canada, poorer sources of uranium ores could be used; even sea water could supply the uranium oxide at only five times the price of the cheapest fuel now mined and, on that basis, there is fuel for centuries: one might thus avoid the development of fast reactors. Another development which will be well investigated in the next decade is the advanced form of converter reactor which economizes in neutron losses and so extracts energy from a few per cent of the heavy uranium isotope. By 1980 many of these matters will be resolved and there are so many variants involved that there is little fear of true duplication occurring in different countries. Prof. Perrin, however, who was president in 1958, sounded a word of warning this time; so much information about power stations and their economic assessment is being kept secret for commercial reasons that this could be very prejudicial to international co-operation.

There are several accounts of adventures being undertaken on a collaborative basis between two or more nations; the *Dragon*, *Vulcain*, and other reactors are described, and Prof. Smyth reviews the development and work of the International Atomic Energy Authority, which is striving for full accountancy of fissile materials in power reactors in the interests of peace. In the 1955 Conference, contributors from very many nations hopefully looked forward to atomic energy to solve their fuel problems; the 1958 Conference showed that there was a long haul ahead; the 1964 Conference is full of optimism again, but as Emelyanov said in his closing remarks, "This is based on a great confidence that nuclear will be the cheapest source of energy" and, indeed, the sole source capable of meeting the requirements of the world.

Prof. Seaborg also spoke of some of the exciting new applications for reactors, such as desalination of sea water ("What is a source of interest to-day could become to-morrow's necessity"), and briefly touched on the few papers given in the short session devoted to fusion research, "one of the most difficult scientific and engineering problems ever encountered". Advances since 1958 have been made in predicting plasma behaviour with good agreement between theory and experiment, in contrast to the situation which prevailed 6 years ago, but "we cannot be sure that fusion can be developed": whether the £30 million per annum being spent on this subject throughout the world is enough just now was questioned.

The volume is full of an immense amount of information well compressed and will be a valuable source book for several years to come. T. E. ALLIBONE

THE NEWTONIAN REVOLUTION

Newtonian Studies

By Alexandre Koyré. Pp. viii + 288. (London: Chapman and Hall, Ltd., 1965.) 50*s*. net.

ALEXANDRE KOYRÉ, who died in Paris in April 1964, started his career as a philosopher, with a particular interest in the philosophy of religion, but later developed a special taste for the history and philosophy of science. On the religious side, he wrote mainly on St. Anselm, various German scholars and mystics of around the sixteenth century, and Descartes. On the scientific side, he dealt mostly with the period which began with Copernicus and ended with Newton. In both contexts, Koyré encountered the work of Descartes, on whom he became a leading authority. At the time of his death, he was collaborating with Prof. I. B. Cohen of Harvard on a critical edition of the Latin text of Newton's *Principia*.

Newtonian Studies contains seven essays, of which six have previously been published in periodicals; three remain in English, and three which were originally published in French are now translated into English. The titles of the six are: "The Significance of the Newtonian Synthesis"; "Concept and Experience in Newton's Scientific Thought"; "Newton, Galileo, and Plato"; "An Unpublished Letter of Robert Hooke to Isaac Newton"; "Newton's 'Regulae Philosophandi'"; and "Attraction, Newton, and Cotes".

However, more than half the book is devoted to a new essay on Newton and Descartes, with no less than thirteen appendixes. Prof. Koyré's excellent qualifications to write on Newton and Descartes will be evident from the brief sketch of his activities given here.

The new essay deals largely with gravitation, as also do several of the appendixes and reprinted essays. The views of Newton and Descartes, and of various other scientists from Copernicus to Leibniz and Samuel Clarke, are discussed on the basis of numerous quoted passages, usually translated into English when necessary, except when the argument turns on niceties of the original language (mostly Latin). This process brings out very clearly the extraordinary strength of the widespread dissatisfaction with the mere use of the inverse-square law as an instrument of calculation.

Newton's mathematical powers, and especially his formidable ability to solve problems without running into error, far exceeded those of any of his contemporaries, and he had discovered an applied mathematical fact of fundamental importance. To us it seems natural that he should confess that he did not understand why planets and satellites should have inverse-square accelerations. Nearly three centuries later, we can see how difficult it is to go beyond what Newton had discovered. The modern worker in astronomical and astronautical dynamics rarely asserts or denies action at a distance explicitly; he merely computes with differential equations which can scarcely fail to encourage him to think habitually in terms of action at a distance for practical purposes. He does so as a first approximation, and is prepared to apply corrections based on Einstein's general theory of relativity in the rare cases in which the corrections are appreciable.

But any empirical procedure seems to have been widely regarded in Newton's time with great repugnance. Desper-

ate indeed were the attempts to explain gravitation by means of mechanisms, often belonging in a general way to the same order of ideas as the vortices proposed earlier by Descartes.

While gravitation bulks largest in Prof. Koyré's book, other Newtonian fields (optics and theology, for example) are by no means neglected. The reader should not be put off by occasional passages in which a nervous style becomes amusing in its qualifications (see, for example, the long sentence on p. 4 which begins "Besides, all of us, or if not all still most of us, have been born and bred —or better and more exactly, not *born* (as this is impossible) but only *bred*—in the Newtonian or, at least, a semi-Newtonian world . . ."). The book is valuable both as a compendium of information (including its numerous references and its many quoted passages made more conveniently accessible) and as an acute discussion of the ideas of Newton and his various adversaries, critics and apologists.

The book is well produced, the printing is excellent, with few misprints, and there is a useful index. I should have welcomed somewhat larger type, especially since the footnotes, which may be described as never occupying more than 90 per cent of the page, are crammed with detail and often call for careful reading. A. Fletcher

FREUD WRITES TO HIS FRIEND

A Psycho-Analytic Dialogue

The Letters of Sigmund Freud and Karl Abraham, 1907–1926. Edited by Hilda C. Abraham and Ernst L. Freud. Translated by Bernard Marsh and Hilda C. Abraham. (The International Psycho-Analytical Library, No. 68.) Pp. xvii+406. (London: The Hogarth Press, and the Institute of Psycho-Analysis, 1965.) 63*s*. net.

A PSYCHO-ANALYTIC DIALOGUE is an interesting book for those wishing to learn of the earlier happenings in psycho-analysis and the personality of the master and his disciples. It consists of letters from Freud to Abraham over 19 years, translated by two different translators in order to give a feeling of individual style. This has been done so well that the impression is of the originals not having been written in a foreign language at all.

If a science consists of the collection of facts, their examination and the meaning deduced from them, and the prediction of further facts as a result, the psycho-analysis can claim to be a science, or at least the beginning of one. The only thing which it lacks is measurement, which must depend on better means of estimating emotion.

Freud and Abraham spent long hours every day in clinical work, in listening to patients talking without guidance in free association. Indeed, Freud says in one of his letters that he has been doing so for 11 hours a day (page 143) and Abraham for nearly as long. Surely this must be regarded as similar to the collection of facts in a laboratory? The formulation of theories to explain what was found led to the body of ideas which is the basis of psycho-analysis to-day.

The discovery of methods to investigate the mind, leading sometimes to cure of the disease, and the potential fields revealed naturally attracted others who were eager to theorize without the trouble of clinical work. This would have led to a distortion of what Freud felt was the basis of his work and naturally he set his face against it. In his letters to Abraham he sometimes releases his irritation for those intruders and expresses his weariness. (This is not surprising when one learns that he was writing books, such as *Totem and Taboo*, as well as seeing patients all day.)

Freud has sometimes been accused of intrigue, although this seems to be contrary to his personality, but in these letters, when dissidents like Adler, Stekel and Jung are mentioned, he does not plot against them, except only inasmuch as he wishes them to leave the movement. Sometimes his language showed his irritation as when he writes of "the brutal sanctimonious Jung", but his efforts are always towards shedding those who will not conform to clinical findings, not their injury.

It would be absurd to pretend that there is a great deal which is very profound in these letters. They are the exchange of comment between two men, one twenty years senior, who are interested in the same work and the same movement. Yet they seem to throw a light on the sort of people they were and the respect which they felt for each other.

They begin with the exchange of letters devoted purely to analytical matters and end on a much more affectionate note, as if Freud had adopted Abraham as a most intimate friend, and Abraham had reciprocated. All through the correspondence there is this friendly note, but Abraham was by no means a mere affirmative to Freud. Indeed, he disagreed strongly in such matters as the personality of Jung and was eventually proved correct in his estimate. A great deal of the contents of Freud's letters has found its way into the various histories of psycho-analysis, but those interested in the original statements will find it fascinating to know what was occurring and said at the time. No one will learn complete psycho-analytical theory from them (although some can be gleaned), but as a study of two eminent men they are of great interest.

C. Allen

BRAIN AND SELF

The Brain and the Unity of Conscious Experience

(The Nineteenth Arthur Stanley Eddington Memorial Lecture, 15 October, 1965.) By Sir John Eccles. Pp. 45. (London: Cambridge University Press, 1965.) 4*s*. 6*d*. net; 95 cents.

SIR JOHN ECCLES's Eddington Lecture for 1965 entitled *The Brain and the Unity of Conscious Experience* is a most distinguished addition to the series. Three-quarters of it is devoted to brilliant and penetrating survey of the latest neurophysiological evidence linking neuronal activity with the existence of conscious states. Much of the work quoted is as yet unpublished, and very important new advances by Moruzzi, Mountcastle, Libet, Myers and Bremer are outlined. Perhaps particularly outstanding is the recent work of Libet and his colleagues, who have utilized the responses of the somaesthetic area in an attempt to discover the nature of the neuronal activity that leads to conscious experience. It was found that with all conditions of threshold stimulation there is a delay of at least 0·5 sec before the onset of the experienced sensation—a sort of 'incubation period' of a conscious experience at threshold level. In the visual system also, there is evidence that at least 0·2 sec of cortical activity is required before the first threshold flash of light can be detected. There is also an excellent account of Sperry's work on the experiences and behaviour of human split-brain patients. This condition in these patients results from the operation of severing the corpus callosum, the anterior commissure and the massa intermedia—an operation which has been highly successful in some cases of severe and long-standing epilepsy.

The final part of the lecture considers whether the uniqueness of the experiencing self derives from genetic uniqueness. Here, Sir John goes back to some little-known, but important, speculations by the eminent American biologist, H. S. Jennings, published in 1930. Since identical twins have identical gene combinations he concludes that these combinations must obviously be compatible with distinctiveness of experiencing selves. He thus concludes that the uniqueness of the individual self cannot be due solely to the uniqueness of the individual gene combination. He further concludes, by what appears to be sound reasoning, that neither can the

accumulated experiences of a lifetime be invoked as the determining or generating factor of the unique self, though naturally they will enormously modify all the qualities and features of that self. He goes on to say that "it is important to recognize that in the first instance this question of the relation of a self to gene combinations can be asked only by an experiencing self of its own existence. For example, I can ask it in relation to my own self, and I reply that I must face up to the problems of my own personal existence as an experiencing self that is dependent on the functioning of a brain, which I try to understand as a biological mechanism; and that my brain has had a biological origin as a consequence of a gene combination and the ensuing embryological development. My experiencing self is the only reality I know by direct apprehension—all else is second-order or derivative reality. The arguments presented by Jennings preclude me from believing that my experiencing self has an existence that merely is derivative from my brain with its biological origin, and with its development under instructions derived from my genetic inheritance. Nor do I believe with the physicalists that my conscious experiences are nothing but the operation of the physiological mechanisms of my brain. It may be noted in passing that this extraordinary belief cannot be accommodated to the fact that only a minute amount of cortical activity finds expression in conscious experience. Contrary to this physicalist creed, I believe that the prime reality of my experiencing self cannot with propriety be identified with some aspects of its experiences and its imaginings—such as brains and neurones and nerve impulses and even complex spatio-temporal patterns of impulses. The evidence presented in this lecture shows that these events in the material world are a necessary but not sufficient cause for conscious experiences and for my consciously experiencing self".

DIET AND DENTAL DISEASE

Nutrition and Caries-prevention

Edited by Gunnar Blix. (Symposia of the Swedish Nutrition Foundation, No. 3.) Pp. 130. (Stockholm: Almqvist and Wiksell, 1965.) 35 Sw.kr.

Caries-resistant Teeth

Edited by G. E. W. Wolstenholme and Maeve O'Connor. (Ciba Foundation Symposium.) Pp. xii+338. (London: J. and A. Churchill, Ltd., 1965.) 60*s*.

THE notion that the form and structure of the teeth, and consequently their resistance to disease, might be influenced by the nature of the diet has long been one that has had many attractions for clinicians and research workers alike. With the familiar examples of pathological changes in bone and other tissues resulting from prenatal and postnatal variations in nutrition, it has seemed natural to assume that the principal dental disease, dental caries, might also be related to dietetic factors. This, of course, has proved to be the case, but not quite in the way expected by some of the earlier researchers. They had felt that nutritional deficiencies might well produce structural defects in the developing teeth of such a kind that susceptibility to caries would be increased. This would be comparable to the increased susceptibility to disease, for example tuberculosis, that is shown by other tissues under conditions of dietary deficiency. However, there is much evidence to show that perfect tooth structure is not essential for resistance to caries and, indeed, life-long immunity to the disease may be exhibited in the presence of comparatively gross structural defects, and in conditions of severe malnutrition. In fact, caries is more prevalent in well-nourished individuals, and is particularly a disease of populations whose standards of living are relatively high. Thus we have what once would have seemed a completely paradoxical state of affairs, that those most susceptible to disease appear to be those who are best nourished. However, the light shed by geographical pathology and epidemiological methods on the incidence of cardiovascular disease and its relationship to diet, on periodontal disease as well as on caries and on other conditions, is bringing home to us, though expressed nowadays in modern and more scientific terminology, the truth of our forefathers' belief that one can dig one's grave with one's teeth.

In *Nutrition and Caries-prevention*, the whole subject of the influence of the diet on caries-susceptibility and resistance is very fully discussed. The book is the record of a symposium sponsored by the Swedish Nutrition Foundation, the range of topics covering practically every aspect of the relationship of diet to caries, including the effect of general nutrition on tooth formation and on the saliva and the oral flora, the local effects of nutrition, the effect of additives to foods and the effects of fluorides both in foods and in water.

The Ciba Foundation's *Caries-resistant Teeth* is another symposium, with a closely related content. Here again, the tantalizing question of individual resistance and susceptibility to disease is posed. Why do the teeth of some people suffer from rapid decay, while those of others, living under apparently identical conditions, seem to be extremely resistant? The effect of diet is discussed, though not of course as extensively as in the previous volume. Other topics dealt with include the role of heredity in caries resistance, the physical and chemical constitution of caries-resistant teeth, including their ultrastructure, the effect of trace elements, the role of bacteria and of saliva, and caries resistance in experimental animals.

In both symposia the participants are experts of international reputation. The papers are well documented and full references are given. The discussion following each communication is also reported. The final result is that these two volumes, though quite independently produced, are in fact complementary, and together give an up-to-date, comprehensive and authoritative account of resistance and susceptibility to the commonest chronic disease of man.

"FRESH AND DRAMATIC"

Research Problems in Biology

Investigations for Students. Series 1. Pp. xxxiii+232. Series 2: Pp. xxviii+240. (Prepared under the direction of the American Institute of Biological Sciences—Biological Sciences Curriculum Study.) (London: George G. Harrap and Co., Ltd., 1965.) 16*s*. each volume.

THE biological world is watching the birth pangs of a new stage in school science. If the parents of this scion, so to speak, are the mid-century centres of biological interest and a coolness towards didactic methods, then the midwife is the pressure of practical developments over the whole range of medicine, agriculture, human biology and a considerable proportion of industry. The new concepts growing out of the interaction of all scientific disciplines rest on the labours of our nineteenth-century post-Darwinian scientific ancestors, and have perhaps few but significant origins in the past half-century. DNA was recognized in 1889, Tansleian ecology emerged in the first 20 years of this century, Mendelism only became current coin after 1900 and electron microscopy since about 1940.

It is against the background of these events that the new teaching has to be evaluated, and since 1958 there have been serious attacks on both the contents of courses and the ways of conducting them. What should schools do? Their responsibility for preparing children for adult life forces them to view science as but one of a number of factors concerned. A fundamental problem is to decide

the relative merits of the various subjects in this preparation and then to give a suitable amount of time and resources to each. At the present time, therefore, we would do well to ask ourselves what are the special qualities that the study of science possesses as compared with classics, languages, mathematics, history and so on. In any case, unless a certain level of scholarship is attained and maintained, and in the widest sense of the term, no subject is of lasting value to the child. We do not start our quest for a new sense of direction and purpose without being the victims of previous educational evolution. There exists an army of teachers of varying ages and experiences as well as laboratories and their equipment, examination boards, and places of higher education, and all combine to form the ultimate source of the scientists the nation needs.

Probably the most comprehensive definite steps taken so far to deal with school biology have been the well-known Biological Sciences Curriculum Studies in the United States. We have had the plan of these before us for some three years and the final editions of the books in the scheme are coming to us now, including the two on *Research Problems in Biology* (*Investigations for Schools*). Our United States colleagues brought much wisdom to their great scheme. They realized that there was a growing gap between the new pattern in biology and the traditional teaching in the schools, and set out to bridge it. At the same time they saw that there was not just one way to present the new ideas. They proposed, in their own words, a "fresh and dramatic approach" based on the view of science as enquiry. In Britain we cannot use the United States works exactly as they stand, partly because they employ American examples, partly because our grammar school system is not the same as their high schools, and partly because university entry needs differ. Thus sooner or later the problem has to be tackled in Britain and the main agency is the Nuffield Foundation's School Science Project. All are naturally watching its activities with sympathy and hoping that its eventual plans will be a useful basis for some of our future work.

It is apt to suggest what might be some of the principles to be borne in mind, for only so can one judge the direction affairs take and their relation to the United States effort. Hitherto, one has worked to a published syllabus and been left free to cover the list of subjects in any way one wished. In order that one's pupils, however, should pass in the G.C.E. examinations, a certain type of coaching has been essential for both the written and the practical examinations. Now there are a number of effective ways of teaching science, and a basic problem is to choose which way is the best for one's own temperament and for each class of individual who comes before one, and there is no one best way. Pure chalk and talk are useful sometimes, while an experimental investigation with the results and method to be worked out and with an unknown result are also sometimes useful. It would be clearly utterly wrong and contrary to the free spirit of science and even to essential human freedoms to dictate only one way from a central authority. It would be a poor country which could not raise teachers so trained as to choose the best way in their own circumstances. Nor is it reasonable to expect an adolescent with a basis of just a few weeks of so-called 'open ended' investigation to establish the principles and concepts of science which it has taken generations of the acutest scientific minds of the world to reach. So the Nuffield workers ought rightly to be subject to fierce scrutiny and so should the architects of new General Certificate of Education work, such as the examining boards.

Again one may ask what is to happen after the Nuffield Project stops. Should university departments of education set up centres where research may go on in conjunction with the suggested special development schools, and is it right that only some schools should be chosen for development?

On looking closely at the two United States volumes which have prompted the foregoing review, one must ask what their part is in the entire plan. They are aimed at the gifted student and comprise some eighty problems by experienced research workers over a wide range of biological science. The books are valuable as a source of ideas, but there are difficulties on the practical side. The precise extent of the ignorance the investigations are designed to eradicate is not clearly stated, and an intelligent student may well ask why he should investigate a matter he knows has been solved. The references given may answer such questions but are often to be found only in good scientific libraries which may not be easily accessible to the school. The teacher is often assumed to have a considerable amount of background knowledge which he must impart to the student before any investigation can begin.

Perhaps a more serious matter is the almost total absence of reference to the dangers involved in having or handling pathogenic materials, and to the lack of indication of the necessity for statistical analyses of results and of their effects on the design of experiments.

However, all pioneering has its rigours and none should be daunted by them. Perhaps the chief significance at the present time is a general awareness of the need for this fresh and dramatic approach and of a change of emphasis. Newman wrote "Lead, kindly Light". No doubt in time we shall see by a new light which will guide us along the very strait and narrow and indeed arduous path which is the adventure we call "science".

GENERAL BIOLOGY

The Biology of Cells

By Prof. Herbert Stern and Prof. David L. Nanney. Pp. xii+548. (New York and London: John Wiley and Sons, Inc., 1965.) n.p.

The Biology of Organisms

By Prof. William H. Telfer and Prof. Donald Kennedy. Pp. xiii+374. (New York and London: John Wiley and Sons, Inc., 1965.) 53*s*.

The Biology of Cells and *The Biology of Organisms* form part of a trilogy (the third on *The Biology of Populations*) in which an attempt is made to break away from the groupings which have traditionally been made in the teaching of biology. Stern and Nanney introduce their book with a general chapter on cell doctrine. This is followed by a chapter on elementary genetics and then, rather surprisingly, eight chapters deal with elementary physical chemistry and biochemistry. After a chapter on information theory, there follow four very good chapters on molecular genetics. The book ends with a section on the organization of cells. Telfer and Kennedy have made one of the first, if not the first, attempts to write an elementary biology text on organisms as a whole, in which sections are not split into botany, zoology, systematics, histology, physiology and so forth. Their section headings are: the problem of diversity; biology of micro-organisms; multicellular organisms; reproduction and development; differential growth; metabolism of multicellular organisms; and integration. Within these sections, plants, animals, structure, physiology and biochemistry are treated as part of a whole aimed at a general understanding of organisms.

Both these books are independent of others but also of each other; consequently, some students might justifiably be inclined to regard each book as sufficient in itself for their course work. However, that of Telfer and Kennedy has a short bibliography and most of their illustrations have detailed references which could enable a student to read further. Rather few of such pointers are found in Stern and Nanney, and expansion of interests

are correspondingly discouraged. The books are well printed, but the point of the illustrations is often lost by the absence of any information of scale. In the texts there is a surprising reticence over the names of the scientists concerned in the work described, unless they be dead.

The books are intended for a freshman reading biology for the first time, and presumably such a student will have no prejudices as to how biology should be presented, provided that it is interesting and stimulating. These texts are interesting and, although there will be complaints that the organisms themselves have been lost in generalities, the authors do not discourage biological novices with overwhelming masses of detailed unrelated facts, as has so often happened in past elementary biology books. However, students may from time to time feel that they would have liked an explanation of the experimental problems involved in obtaining the facts described—a particularly important point for those familiar with the techniques of physical sciences but unfamiliar with the rather different technical problems of a biologist. Much of the interest and use of these books in Britain, particularly that of Telfer and Kennedy, will be for those of our school science sixth-forms and universities where attempts are being made to replace the traditional presentation of biological (and for that matter medical) curricula. In the design of such courses, these books should be carefully examined.

CAPTIVE ANIMALS

Animals in Captivity

By Philip Street. Pp. 231+24 photographs. (London: Faber and Faber, Ltd., 1965.) 25*s*. net.

KEEPING wild animals in captivity is an ancient art and it flourished in several long-lost civilizations. *Animals in Captivity* is concerned with its history in modern Europe, and primarily in Britain. The only continental zoo treated in any detail is Hamburg, where the Hagenbecks added immensely to practical knowledge about the keeping of captive animals, especially the larger species. The founder of the family can rightly be regarded as the father of modern zoos and circuses, and if more of his ideas had been adopted much better progress in this field would have been made.

Nearly a century ago, Hagenbeck saw the need and possibility of acclimatization. For monkeys he advocated a cage temperature of around 60° F, with flaps giving access to fresh air; they used them, even with the thermometer below zero. A few pages later Mr. Street quotes from the Centenary History of the Zoological Society of London. One of the big problems awaiting Chalmers Mitchell in 1903, when he began his long and successful tenure, was that keepers insisted that all tropical animals be kept warm, even if it meant sealing all windows. This attitude is still widely persistent.

Whipsnade is rightly portrayed as a trend-setter of great importance, but its original purpose—the provision of a rest centre for London animals—has been superseded by more useful objectives. A forcible change of scene upsets wild animals more than it helps them. Many aspects of the subject are dealt with adequately, but the book disappoints in its major omissions, and it could almost have been written 10 or 20 years ago. The bird chapter makes no mention of 'walk-through' flight aviaries. The names of Hediger and Grzimek cannot be found, but their contributions have been of incalculable value. The former's work on the psychology of animals in zoos is fundamental, while Grzimek has rebuilt the bombed Frankfurt Zoo into one of the world's outstanding collections, with a fresh approach to many housing problems.

Under the heading of health and food the work at the Philadelphia Zoo finds no place, yet the balanced diets devised in the laboratory there have given a completely new shape to longevity and breeding statistics wherever the system has been adopted. These and other recent developments could well have replaced long passages on minor matters. The illustrations, mostly by the author, are excellent, and there is an index, but no bibliography.

George Cansdale

A FOUNDATION STONE OF PHYCOLOGY

The Structure and Reproduction of the Algae

By F. E. Fritsch. Vol. 1: Pp. xvii+791. Vol. 2: Pp. xiv+939. (London: Cambridge University Press, 1965.) 90*s*. net per volume.

IN the twenty years which have elapsed since the publication of the second volume of *The Structure and Reproduction of the Algae*, the study of these plants—phycology as it is now fashionable to call it—has undergone profounder change and greater expansion than it did in the forty years which separated the completion of Fritsch's work from that of its forerunner, Oltmann's *Morphologie und Biologie der Algen*. Chemical investigation and the electron microscope have revealed in their different ways an underlying unity of basic structure and fantastic diversity of detail which in 1945 could be only dimly suspected. Algae, some species of which have for a long time been used as convenient experimental material for investigation of some of the classical problems of plant physiology, now engage the attention of the physiologist and biochemist in a more general way, and a large body of publications has appeared showing that their functioning and metabolism have intrinsic interest as great as that of any group of organisms. Phytoplankton still remains the form of plant life receiving least attention from the botanist, but whole new classes of plankton algae have been defined and important advances have been made in understanding their ecology, much of this depending on culture techniques, the use of which Fritsch himself did so much to encourage. Side by side with these developments, which are largely new since 1945, description of species and elucidation of life-cycles by classical method have been progressing steadily.

Nevertheless, Fritsch's two volumes continue to figure in the reference lists of research papers, ecological and physiological as well as morphological; they are constantly brought out in the practical class as the final arbiter on most points relating to algae; and there is no doubt that this present reprinting is both welcome and justified. Partly this is because the foundations of phycology have always been to a remarkable extent broadly based and have stood the test of time. From the beginning, almost, biochemical characteristics have ranked equally with morphological features in algal taxonomy. Phycology has been fortunate in having had many distinguished exponents who, like Fritsch, remembered the ecology and physiology of the organisms they investigated and encouraged others to investigate these, even though their own primary interest was in other aspects.

In addition to wideness and balance of outlook, Fritsch's writing displays meticulous scholarship. Misprints presumably must occur in a work of this length, but I cannot recollect having found one, or any misquotation of fact or reference.

The Structure and Reproduction of the Algae is undoubtedly out of date in detail, and in particular the physiology which it includes has an old-fashioned look, but an account so soundly constructed will certainly continue to serve as a basic text for a long time. Unfortunately, another Fritsch would be required to revise it adequately.

G. E. Fogg

HELIUM PRODUCTION IN AN ANISOTROPIC BIG-BANG COSMOLOGY

By Dr. S. W. HAWKING and Dr. R. J. TAYLER

Department of Applied Mathematics and Theoretical Physics, Cambridge

THERE has recently been much interest in the helium content of the universe. A variety of observations, mainly on objects in our own Galaxy but some of nearby galaxies, have suggested that the helium abundance relative to hydrogen may be rather uniform with about one helium atom to every eleven hydrogen atoms. If such an abundance were universal, except for local irregularities mainly with a higher helium abundance, it would mean that about 27 per cent by mass of the universe is helium and it would seem plausible that the general helium abundance has been produced cosmologically, and that the local irregularities are due to helium production in stars or similar bodies.

If the universe had a singular origin with high temperature and density ('hot big-bang' theory), some helium would have been produced in the first few minutes. The amount of helium produced depends on the ratio of material energy density to radiation energy density in the early stages of the expansion of the universe but for quite a wide range of matter densities essentially the same amount of helium is produced. In the early calculations of Hayashi[1] and Alpher, Follin and Herman[2], this plateau helium abundance was about 40 per cent by mass. More recent calculations by Hoyle and Tayler[3], Smirnov[4] and Peebles (personal communication, 1965) suggest that the value should be about 35 per cent, but there are still some uncertainties in the theory. It seems somewhat unlikely, however, that the errors in theory and observation are sufficient for the true plateau helium abundance to be lower than the observed abundance.

If the initial matter density is taken low enough it is possible to produce a smaller amount of helium and one which would fit the observations. However, there is a further difficulty. It appears that the expansion of the big-bang fireball should leave a low-temperature thermal radiation field in intergalactic space. The value to be expected for the radiation temperature with the present material density depends on the initial matter density. If the latter were low enough for the initial helium abundance to be 27 per cent by mass or less, it seems that the present-day radiation temperature should be at least 10° K and possibly 20° K. Several measurements have been made recently which suggest that there is a universal radiation field and which are certainly not inconsistent with its being black body at about 3° K (refs. 5–7). It now seems unlikely that the conventional hot big-bang theory will be able to give correct values for the helium abundance and the cosmic radiation temperature.

Although the situation is not quite clear, it seems worth while to consider whether there are any modifications to the theory which retain the essential feature of the hot singular origin to the universe and at the same time offer hope of reconciling the results. Two possibilities immediately present themselves. The amount of helium produced would certainly be affected if the Newtonian gravitational constant were not a true constant but was larger in the early stages of the universe as has been suggested by several authors[8,9]. The other possibility is that the universe has not always been isotropic. Observations of distant galaxies and radio sources suggest that the universe has been isotropic for most of the lifetime of an evolving universe, but there are certainly no observations to show that it was isotropic in its earliest stages. It is a possibility, although perhaps not a very attractive possibility, that the universe was anisotropic when created but that the anisotropy rapidly disappeared in the expansion. It is the purpose of this article to point out that the existence of such an anisotropy, even if it only persisted for a few years, could have had a profound effect on the helium production.

The Early Stages of an Anisotropic Universe

It is well known that, in the early stages of the expansion of a homogeneous, isotropic, hot big-bang universe in which radiation energy density dominates over material energy density, there is a unique relation between temperature and time. Hoyle and Tayler[3] give the relation in the form:

$$T = 1{\cdot}04 \times 10^{10}\, t^{-\frac{1}{2}} \qquad (1)$$

where T is in °K and t in sec. The exact value of the multiplicative constant (1·04) depends on the assumption that the photon field is enhanced by positrons, electrons, neutrinos, antineutrinos, μ-neutrinos and anti μ-neutrinos at high temperatures.

The particular solution (1) of the relativistic equations is that which satisfies the initial conditions, $T \to \infty$ as $t \to 0$. If the universe is initially anisotropic but rapidly tends to isotropy, a solution of the isotropic equations is still required, but it can be the more general one:

$$T = 1{\cdot}04 \times 10^{10}\, (t+\alpha)^{-\frac{1}{2}} \qquad (2)$$

where α is an arbitrary constant.

If the universe is initially anisotropic, with expansion from a two-surface rather than a point, the relation between temperature and time takes a form different from (1):

$$T = \beta t^{-\frac{1}{2}} \qquad (3)$$

where now β is a parameter which depends on the type or degree of anisotropy. In the earliest stages the relation (3) will hold and, when the anisotropy disappears, a relation of the form (2) will be valid. The relations (1), (2) and (3) are shown in Fig. 1.

An approximate estimate of the duration of the anisotropy for given β is obtained as follows. It seems plausible that the change-over from the law (3) to (2) should occur smoothly. This implies, as can be seen from Fig. 1, that α is positive. For given β it is possible to choose a time t_0 and a value of α so that a change-over from (2) to (3) occurs

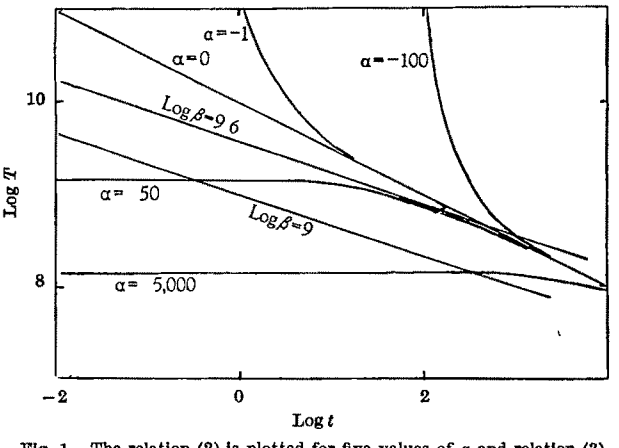

Fig. 1. The relation (2) is plotted for five values of α and relation (3) for two values of log β. The change-over from anisotropy to isotropy is shown for $\alpha \approx 50$, $\log \beta \approx 9{\cdot}6$

with T and dT/dt both continuous. This time t_0 should be a reasonable first approximation to the time at which the anisotropy disappears. A more accurate value will only be found by integrating the anisotropic cosmological equations. This matching of the relations (2) and (3) gives the results:

$$\left.\begin{aligned} t_0 &= \frac{8(1{\cdot}04\times10^{10})^6}{27\beta^6} \\ \alpha &= \tfrac{1}{2}t_0 \end{aligned}\right\} \qquad (4)$$

In Table 1 are shown, for several values of β, t_0 and the times at which $T=10^{10}$ °K and 5×10^8 °K. It can be seen that, even if the anisotropy lasts for only a few hours, the time taken to reach temperatures such as 5×10^8 °K is considerably reduced.

It should be pointed out that, whether the universe is isotropic or anisotropic, provided no nucleon creation occurs, there is the relation:

$$n \propto T^3 \qquad (5)$$

between nucleon number density and temperature. This means that, if we now consider a set of anisotropic universes characterized by the same present values of radiation temperature and matter density, they will have the same matter density at any higher temperature; only the time-scale is different. Let us consider the rate of formation of helium at high temperatures and densities. The first reaction that must occur is:

$$n+p \rightarrow D+\gamma \qquad (6)$$

and to a good approximation we may take the value of $<\sigma v>$ for this reaction to be independent of temperature at the temperatures of interest. The value adopted is 7×10^{-20} (W. A. Fowler, personal communication, 1965). Table 2 shows the characteristic time-scale of this reaction at a temperature of 10^{10} °K for a present-day radiation temperature of 3° K and for several values of the present-day matter density which cover the range of values which is believed plausible. It can be seen that this reaction, which is an essential preliminary to the production of helium, will scarcely go at 10^{10} °K for any of the densities if the anisotropy lasts for 10 years or more; this follows from a comparison of reaction times in Table 2 and evolution times in Table 1. While the universe remains anisotropic the reaction time and evolution time are directly proportional, so that if the reaction will not go at 10^{10} °K it will not go at any other temperature while the anisotropy remains. Even more so is this true when isotropy takes over, for then the reaction time steadily gets larger compared with the evolution time. It thus appears that, if the anisotropy lasted longer than something of the order of 10 years, essentially no helium would have been produced in the big bang.

Table 1

Log β	$t(10^{10}$ °K)	$t(5\times10^8$ °K)	t_0
8	10^{-6}	8×10^{-3}	4×10^{11}
8·5	3×10^{-5}	$2{\cdot}5\times10^{-1}$	4×10^{9}
9	10^{-3}	8	4×10^{5}
9·5	3×10^{-2}	$2{\cdot}5\times10^{2}$	4×10^{2}
10	9×10^{-1}	4×10^{2}	4×10^{-1}
Isotropic	1	4×10^{2}	0

Table 2. Reaction Times for the Production of Deuterium at 10^{10} °K for a Present-day Radiation Temperature of 3° K and for Several Values of the Present Nucleon Density (n)

The actual values are obtained by taking $<\sigma v>=7\times10^{-20}$ and $n_p=3n_n$.

n(3° K)	$n(10^{10}$ °K)	t Reaction
10^{-5}	4×10^{23}	5×10^{-5}
10^{-6}	4×10^{22}	5×10^{-4}
10^{-7}	4×10^{21}	5×10^{-3}

If the anisotropy does not last long enough to ensure that little or no helium is produced, it might be thought that an amount less than the isotropic value would be produced. However, it seems that for some values of the anisotropy parameter the helium production exceeds that in the isotropic case. The reason for this is as follows. In the isotropic case the helium producing reactions which follow reaction (6) are rapid and (for values of the matter density which yield a present radiation temperature of 3° K) the amount of helium produced is essentially determined by the number of neutrons when reaction (6) and the subsequent reactions become important. If the universe is slightly anisotropic the early stages of the expansion are speeded up but perhaps not sufficiently to prevent complete burning of neutrons. However, any speeding up of the expansion makes it more difficult for the reactions changing neutrons into protons, and this means that, at a given temperature when deuterium and helium production start, the neutron density is higher than in the isotropic case. As the anisotropy parameter $(1/\beta)$ increases from zero there should thus be an initial rise in helium production while the greater neutron density is the dominant factor and the subsequent fall should occur when the anisotropy parameter is large enough for reaction times to exceed the evolution time.

Homo habilis, *Homo erectus* AND THE AUSTRALOPITHECINES

By Dr. L. S. B. LEAKEY

National Museum, Centre for Prehistory and Palaeontology, Nairobi, Kenya

TOBIAS[1], in his reply to Robinson[2], has dealt very adequately with his questions about the validity of our new species of *Homo*, and I heartily agree with his arguments that *Homo habilis* stands completely distinct from any *Australopithecus*. I would like, however, to stress certain of the morphological aspects in which the mandible of the australopithecines differs from that of *Homo sapiens*, *Homo erectus* and *Homo habilis*, all three of which share *Homo* features.

These basic features can be clearly seen in Figs. 1 and 2. The "V"-shaped structure of the australopithecinae is illustrated by a specimen of the so-called 'gracile' species, *Australopithecus africanus*, and the mandible of *Australopithecus* (*Zinjanthropus*) *boisei* from Peninj. Contrasted with them we have in Fig. 1 the mandible of the paratype of *H. habilis* from Olduvai site *MNK* II and a specimen of *H. sapiens*. In Fig. 2 we have views of three species of *Homo*—*erectus*, *sapiens* and *habilis*—contrasted with *Australopithecus* (*Zinjanthropus*) *boisei*. Comparing Figs. 1 and 2 there can be no doubt that at least the paratype of *H. habilis* from *MNK* II belongs with the genus *Homo*, not with *Australopithecus* (not even the species *africanus*).

Similarly, if the views of the two species of *Australopithecus* in Fig. 1 are compared with Tobias's illustration of the type of *H. habilis*, the same conclusion must be drawn.

It must here be noted that it was this striking difference in mandibular structure which, among other factors,

rightly led Broom and Robinson to separate what used to be called *Telanthropus capensis* from the genus *Australopithecus*.

Examination of illustrations 1 and 2 seems to me to eliminate Robinson's view that *H. habilis* is nothing but a variant of *A. africanus*, or, as he has more recently suggested, that *A. africanus* is really *Homo*. *H. habilis*, however, in its mandibular structure, is unquestionably of *Homo* type. It shares features with both *H. sapiens* and *H. erectus* and is quite distinct from any australopithecine species so far described.

I wish next to make it clear that I do not share the opinions of my colleague Tobias, which he expressed in Moscow[3] and elsewhere (and some of which he reiterated in the closing stages of his reply to Robinson), when he comes to deal with the relationship of the australopithecines to the genus *Homo* or of *Homo habilis* to *Homo erectus*.

Tobias holds the view that the evolution of Man has been through a series of 'stages' represented, respectively, by *Australopithecus africanus* and *H. erectus*, leading on to *H. sapiens*. He goes further and expresses the opinion

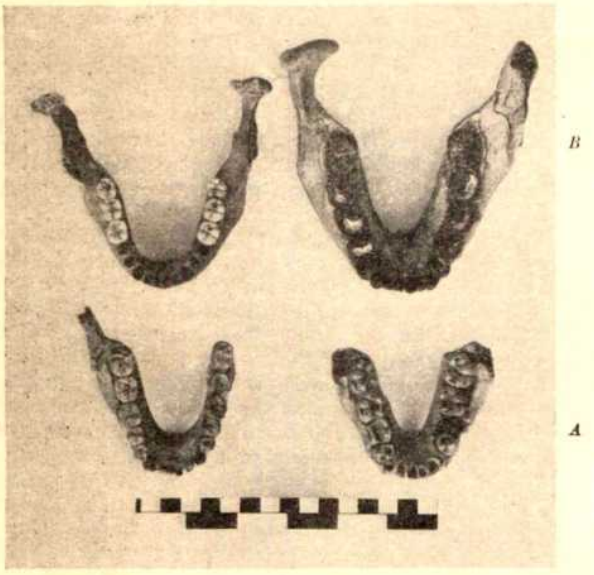

Fig. 1. Mandible of: *A, Australopithecus africanus; B, Australopithecus (Zinjanthropus) boisei; C, Homo sapiens; D, Homo habilis*

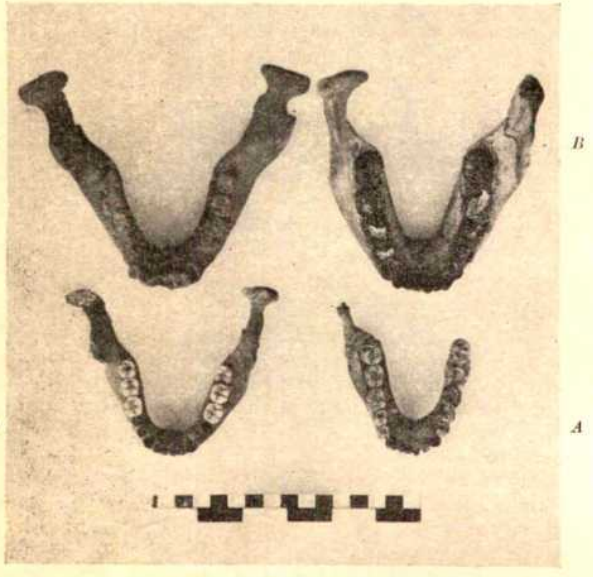

Fig. 2. Mandible of: *A, Homo habilis; B, Zinjanthropus; C, Homo erectus*/North Africa; *D, Homo sapiens*

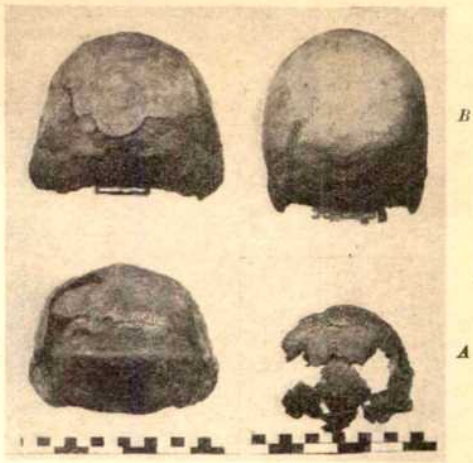

Fig. 3. Occipital views of: *A, Homo habilis; B, Homo sapiens; C, Homo erectus*/Olduvai *LLK; D, Homo erectus*/China

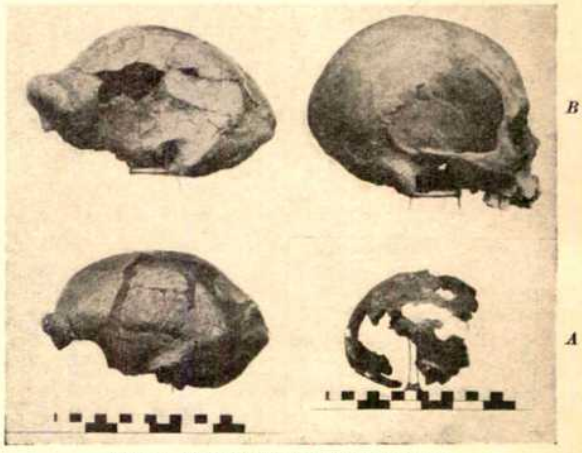

Fig. 4. Same as Fig. 3 but profile views

that "*Homo habilis* may represent a stage between *Australopithecus africanus* and *Homo erectus*".

I do not believe that the available evidence in any way supports such a conclusion. It seems to me more likely that *H. habilis* and *H. erectus*, as well as some of the australopithecines, were all evolving along their own distinct lines by Lower Pleistocene times. This would mean that their shared common ancestor must be sought in the more remote past and that when examples of the parent stock are found they will not much resemble any one of the three subsequent branches.

I submit that morphologically it is almost impossible to regard *H. habilis* as representing "a stage between *Australopithecus africanus* and *Homo erectus*". In both the two latter hominids, the maximum cranial width is to be found near the base of the skull on the temporal bones. *H. habilis*, on the other hand, shares with *H. sapiens* the characteristic of having the greatest width of the vault on the parietals (see Figs. 3–6). *H. habilis*, also, shares an occipital morphology with *H. sapiens*, which, moreover, is quite unlike either *H. erectus* or any known australopithecine. It therefore seems to me most unlikely that the *H. habilis* cranial structure—either parietal, occipital or basi-occipital—could represent a stage "intermediate between *Australopithecus* and *Homo erectus*".

Even though *H. erectus* and the australopithecines share a number of cranial characters in their occipital bones, and in having a maximum width at the base of the skull, I have never been able to accept the view that *Australopithecus* represented a direct ancestral stage leading to *H. erectus*, and I disagree even more strongly with the present suggestion of placing *H. habilis* between

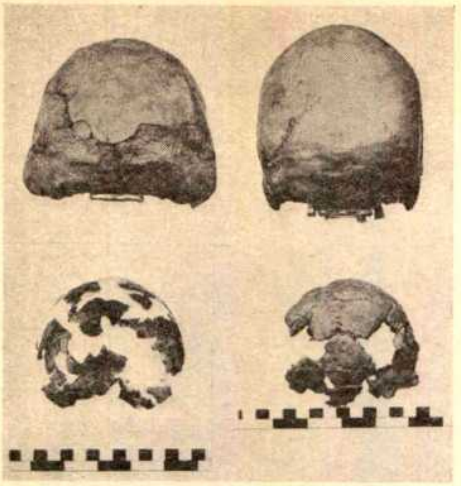

Fig. 5. Occipital views of: *A*, *Homo habilis; B, Homo sapiens; C, Homo erectus*/Olduvai *LLK* II; *D*, Protopithecanthropine

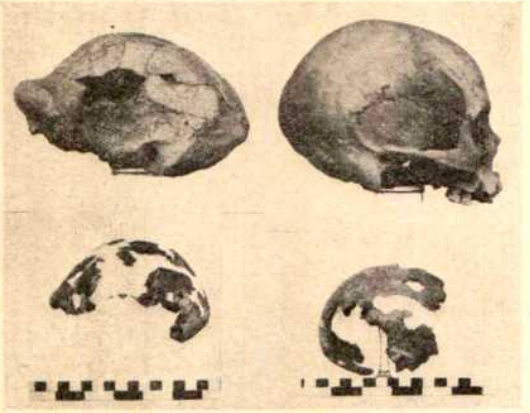

Fig. 6. Same as Fig. 5 but profile views

them. It places a hominid type which has a wholly distinct cranial morphology and one recalling that of *H. sapiens* type between these two. It is possible that *H. habilis* may prove to be the direct ancestor of *H. sapiens*, but this can be no more than a theory at present. If true it would mean that there had been two distinct species of the genus *Homo* at a very early stage—one leading to *H. erectus* and subsequent extinction and the other to *H. sapiens*.

We must also take into account the fact that at the very base of Olduvai Bed II, at *FLK* Maiko Gully, we have a skull, as well as the greater part of the associated dentition, of what seems to be an ancestral stage of *H. erectus* (see Fig. 6). This specimen was found stratigraphically between the earlier and the later representative of *H. habilis*, which also makes it unlikely that *H. habilis* evolved from a pithecanthropine.

On the other hand, it does suggest that there were two parallel species of the genus *Homo* evolving at Olduvai, one from the earlier to the more advanced *H. habilis* and the other from the protopithecanthropine to the very specialized representative of the African variety of *H. erectus*, which is represented by the skull from Olduvai *LLK* II.

The stratigraphical position of the different hominid finds from Olduvai, that are referred to in this article, is shown in Table 1. Table 1 includes the *Zinjanthropus* mandible from the nearby Peninj site, where the combined evidence based on geology, fauna and culture suggests a correlation with the Middle and Upper part of Bed II, Olduvai.

Table 1. Stratigraphical Relationships of Hominid Finds at Olduvai and Peninj

Type of hominid	*Homo habilis*	*Pithecanthropine sensu Lato*	*Australopithecus* (*Zinjanthropus*)
Main Bed II and its Peninj equivalents	+ *MNK* II	+ *LLK* II	+ *BK* II + Peninj
Lower Bed II	Major climatic break	+ *FLK* II Maiko Gully	
Bed I	+ *FLK NI* ? + *FLK* I + *FLK NN* I + *MNK* I		+ *FLK* I
	LAVA		

Table 1, taken in conjunction with the morphological factors briefly summarized here which are clearly seen in Figs. 1–6, should serve as a deterrent to the many who would like to draw up evolutionary sequences based on insufficient numbers of specimens.

All that need be said at present is that there was a time at Olduvai when *H. habilis*, *Australopithecus* (*Zinjanthropus*) *boisei* and what seems to be a primitive ancestor of *H. erectus* were broadly contemporary and developing along distinct and separate lines.

CLOTHING INSULATION AND ACCIDENTAL HYPOTHERMIA IN YOUTH

By L. G. C. PUGH

Division of Human Physiology, National Institute for Medical Research, Hampstead, London, N.W.3

An investigation was undertaken with the view of improving our understanding of the environmental factors concerned in exposure accidents among hill-walkers and climbers in Britain. The effects of exercise, wind and wetting on the thermal insulation of a typical clothing assembly were observed. The clothing examined had been worn by one of the youths who died of exposure on the 'Four Inns Walk' in Derbyshire in March 1964 (ref. 1). It consisted of the following items: anorak with hood, woollen jersey, 'Vyella' type shirt, string vest, cotton drawers, jeans, one pair of socks, shoes and gloves. The experiments were conducted in a small climatic chamber in which a minimum temperature of 10° C (relative humidity 50 per cent) and a maximum wind velocity of 8·9 m.p.h. were obtainable.

The subject was a normal adult aged twenty-one. His height was 182 cm, weight 80·5 kg, surface area 2 m² and mean subcutaneous fat thickness 7·9 mm. He was examined at rest and during standard exercise on a bicycle ergometer at a work rate of 300 kg/min. The experiments were carried out in 4·5 h sessions beginning between 1200 h and 1300 h. The ambient temperature was 9·4° C dry bulb and relative humidity 50 per cent. The following experimental situations were investigated. (1) Rest in a

sitting posture: (*a*) at air movement 12 ft./min; (*b*) at air movement 220 ft./min (2·5 m.p.h.). (2) Exercise in still air. (3) Exercise in a wind of 790 ft./min (9 m.p.h.) velocity. (4) Exercise in a 9 m.p.h. wind after the clothing had been saturated with water by standing under a shower bath, the water temperature being either 10° C or 18° C. (5) As under (4), but wearing a plastic over-anorak and windproof over-trousers which kept the clothing dry.

The experiments were conducted in the following order: Day I, situations (2), (3) and (4). Day II, situations (1*a*) and (4). Day III, situations (1*b*) and (5). A final experiment was carried out in less well-controlled conditions in a laboratory at an ambient temperature of 16° C, relative humidity 60 per cent, and air movement 25 ft./min.

Measurements of rectal and body surface temperature were begun after 40 min in each situation and repeated at intervals of 20–30 min for 90 min at rest and 73 min during exercise. Rectal temperature was measured with an indwelling thermocouple at a depth of 15 cm. Skin temperatures were measured with a thermocouple probe inserted through small holes in the clothing or held in contact with the exposed skin. A Cambridge potentiometer was used for measuring rectal temperatures and an 'Ellab' thermocouple thermometer (Elecktrolaboratoriet, Copenhagen) for skin temperatures. When the subject's clothing was wet the skin temperatures of the lower limbs and extremities fell below 16° C and could not be measured with the probe. The experiment was repeated with thermocouples attached to the skin, and readings were taken on the Cambridge potentiometer.

The respiratory exchanges were measured by the bag method before each set of temperatures; expired gas was collected over 15 min in resting experiments and 4–6 min in work experiments. Gas samples were analysed on a Lloyd–Haldane apparatus.

The rate of heat loss in warming and saturating inspired air was calculated from the formulae given by Belding *et al.*[2]. Evaporative heat loss from the skin was assumed to be constant at 18 g/h[2].

0·6	75	39	0·85
0·8	35	18	0·4
1·0	10	5	0·1

Mean skin temperatures were computed from 2–4 readings taken over each of thirteen regions of the body surface using the weighting factors shown in Table 1. Mean body temperature (T_B) was calculated as 2/3 rectal + 1/3 skin temperature. Skin temperature, for this purpose, was computed without the extremities, the weighting factors being adjusted accordingly[3,4]. Stored heat loss (S) was computed from the following equation:

$$S = \Delta T_B \times W \times 0{\cdot}83 \times \frac{60}{t} \qquad (1)$$

where ΔT_B is the change in mean body temperature in time (t) min, W is the body-weight in kg, and 0·83 the specific heat of tissues in kcal/kg.

The insulation value of the clothing was calculated as follows:

$$I_{Cl} + I_A = \frac{T_S - T_A}{0{\cdot}18\,H} \qquad (2)$$

$$H = \frac{M - W - E - S}{S.A.} \qquad (3)$$

where I_{Cl} is the insulation value of clothing (in Clo units); I_A the insulation value of air (in Clo units); T_S, the mean skin temperature (in °C); T_A, the ambient dry bulb temperature (in °C); H, the non-evaporative heat loss through clothing (in kcal/m² h); 0·18, the factor for converting c.g.s. units $\left(\frac{°C}{\text{kcal/m}^2\text{ h}}\right)$ to Clo units; M, metabolism (in kcal/h); W, mechanical work (in kcal/h—1 kcal = 427 kg/min); E, evaporative heat loss from lungs and skin plus heat loss in warming inspired air (in kcal/h); S, stored heat loss (in kcal/h); $S.A.$, surface area (in m²).

From the same data it was possible to calculate values for the insulation (I_T) and conductance (K) of the tissues, thus:

$$I_T = \frac{T_R - T_S}{H}, \text{ in } \frac{0°\text{ C}}{\text{kcal/m}^2\text{ h}} \qquad (4)$$

and

$$K = \frac{H}{T_R - T_S}, \text{ in } \frac{\text{kcal/m}^2\text{ h}}{°\text{C}} \qquad (5)$$

In the calculation of H in equations (4) and (5) evaporative heat loss from the skin was omitted.

Clothing and air insulation (I_{Cl} and I_A). The effect of exercise, wind and wetting on the insulation afforded by clothing and air is illustrated in Fig. 1, and compared with the values observed when the subject was at rest in 'still' air (that is, less than 25 ft./min of air movement). The numerical data from which these results were calculated are shown in Table 2. An estimate of the *S.D.* of a single measurement based on six pairs of observations was ± 0·10 Clo.

Rest. In 'still' air in the climatic chamber the total insulation afforded by the dry clothing and surrounding air ($I_{Cl} + I_A$) was 2·49 Clo (Table 2, No. 2). A com-

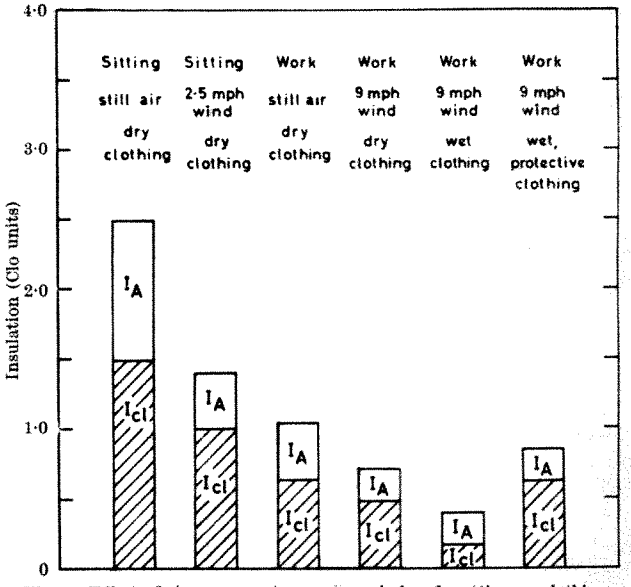

Fig. 1. Effect of air movement, exercise, wind and wetting on clothing and air insulation ($I_{Cl} + I_A$). With wet clothing in the presence of wind, overall insulation was comparable with that of air alone at low wind velocity

parable result was obtained under ordinary conditions in the laboratory (Table 2, No. 1). From Table 1 the value of I_A for still air is 1·0 Clo, therefore I_{Cl} was equal to 1·49 Clo. This result may be compared with the standard value of 1 Clo for ordinary business clothing[4], and 3 Clo for military polar clothing[5,6]. With modern down clothing, values up to 7 Clo have been obtained.

In a slight breeze (wind velocity 2·5 m.p.h.) $I_{Cl} + I_A$ fell to 1·40 Clo. The value of I_A at this wind velocity is 0·4 Clo; therefore, the value of I_{Cl} was 1·00. This 30 per cent drop in I_{Cl} was associated with a marked fall in skin temperature over the face and extremities and to a lesser extent over the limbs.

Exercise. During exercise in 'still' air $I_{Cl} + I_A$ fell to 1·04 Clo, a finding which could be attributed to the 'bellows' action of movement in displacing static air from the clothing. I_{Cl} could not be estimated for this situation, since the effect of exercise on I_A is not known. However, a likely value of 0·4 Clo has been assumed for the purpose of illustration (Fig. 1).

The combination of wind and exercise reduced $I_{Cl} + I_A$ to 0·71 Clo.

Wetting. When the subject worked on the ergometer wearing wet clothing and facing a 9 m.p.h. wind, $I_{Cl} + I_A$ fell to 0·4 Clo. Wetting therefore reduced total insulation by 0·7 − 0·4 = 0·3 Clo, or nearly 50 per cent, and if I_A is assumed equal to 0·23 Clo, which is the appropriate value for a wind velocity of 9 m.p.h., the value of I_{Cl} is only 0·17 Clo, which is only 15 per cent of the insulation value of this clothing, when dry and in the absence of wind or exercise.

When the subject wore waterproof over-garments which kept his clothing dry and at the same time protected him from the wind, $I_A + I_{Cl}$ rose to 0·85 Clo, which was close to the observed value for exercise in dry clothing in still air.

Change of stored heat (S). The values of S in most of these experiments were within the limits of experimental error (Table 2), indicating that a state of thermal equilibrium had been reached. This was achieved in 1–1·5 h in the resting experiments and in about 45 min during exercise. In two experiments a steady state was not achieved; in one of these (experiment 3) clothing insulation was inadequate for the conditions (ambient temperature, 10° C; air movement, 2·5 m.p.h.); in the other there was an excess of stored heat from a previous 15-min period of exercise at 600 kg/min before the experiment.

Skin temperature. The regional and mean skin temperatures observed at the end of each experimental period are shown in Table 3. The resting mean skin temperature at a comfortable ambient temperature of 16° C was 32·1° C, which was lower than expected since the values observed in clothing experiments in comfortable temperatures are usually in the range 33°–34° C. This finding

	Wet and wind with protective over-garments	14/4/65	34·7	31·8	27·0	22·4	18·9	13·7

Note the low skin temperatures over the limbs associated with the wearing of tight jeans. The fall in trunk temperature in the presence of wind (5) shows that the anorak was inadequate. The low trunk and peripheral temperatures seen with wet clothing indicate severe cold stress.

was explained by the comparatively low temperatures over the lower limbs and the fact that the subject was rather fat[7]. In a group of middle-distance runners recently examined, mean subcutaneous fat thickness was 3·2 mm (range 3·8–2·9 mm)[8], compared with 7·9 mm in this subject.

Oxygen intake. During rest at an ambient temperature of 9·4° C, the subject felt cold, and although shivering was not perceptible, there was considerable elevation of metabolism. Mean oxygen intakes of 0·424 l./min and 0·385 l./min were observed on different days, compared with 0·300 l./min in a warmer environment in the laboratory, the latter being the predicted value for conditions of thermal comfort.

When the subject's clothes were dry and he was exercising in 'still' air or wore protective over-garments in the presence of a 9 m.p.h. wind, mean oxygen intakes of 0·99 l./min–1·10 l./min were observed (Table 4), these being typical values for the 300 kg/min work-rate. When his clothes were wet and he exercised facing a 9 m.p.h. wind, the subject experienced severe cold stress. The measured work-rate increased by 25 per cent due to faster pedalling, and the oxygen intake rose by 50 per cent to 1·50 l./min, which was the predicted value for twice the work-rate (that is, 600 kg/min). Since there was no perceptible shivering, the reason for this disproportionate increase in oxygen intake was not apparent. A similar effect was observed by Adolph and Molnar[9] in their experiments on nude subjects in the cold, and is important in that it affords a partial explanation of early exhaustion in exposure accidents.

Table 4. Oxygen Intake and Observed Work-rate during Exercise at a Nominal Intensity of 300 kg/min, Showing Influence of Cold Stress.

Conditions	Date	Observed work-rate (kg/min)	Oxygen intake (l./min S.T.P.)
Dry clothing, minimal air movement, no cold stress	28/4	294	1·009
	30/4	283	0·986
	14/5	291	1·096
	Mean		1·030
Wet clothing, wind, cold stress + +	28/4	309	1·501
	30/4	386	1 511
	30/4	337	1 575
	Mean		1 529

Tissue conductance and insulation. The resting values of tissue conductance (K) and its reciprocal tissue insulation (I_T) are shown in Table 2. The resting values compare well with published data on the minimum tissue conductance or maximum tissue insulation of resting subjects exposed in air[10,11] or in water[12,13], and suggest that cutaneous vaso-constriction was maximal in all the resting experiments[14]. The results observed during exercise in wet clothing agree with minimum values calculated from the data of Nielsen[15] and Adolph and Molnar[9] for subjects exercising in the cold air at low temperature. They show a 30 per cent increase in conductance over the resting values. This is less than the increase in K reported in swimmers in cold water[16].

The foregoing results show satisfactory agreement with published data on military clothing. Belding[5] reported a 50 per cent reduction in I_{cl} associated with exercise, but there is as yet no satisfactory estimate of the effects of exercise on I_A. Breckenbridge and Woodcock[6] measured the effect of wind on the insulation of military cold-weather uniforms and observed a 30–40 per cent reduction at a wind velocity of 24 m.p.h. These uniforms had windproof trousers and were superior in many respects to the 'Four Inns Walk' clothing. Larose[17] has shown that in some fabrics, such as pile, the insulation is but little affected by winds up to 10 m.p.h. but falls steeply at higher velocities as the wind begins to penetrate the fabric. The best windproof fabrics now available show less than 1 per cent penetration at 100 m.p.h. wind velocity and yet are permeable to water vapour. Hall and Polte[18] and Hall *et al.*[19] reported a 50 per cent reduction of insulation associated with wetting. But no previous measurements have been reported on the combined effect of wind and wetting on clothing insulation.

The conditions of our experiments differed in many ways from outdoor conditions. The effects of wind and exercise are likely to be greater in hill walkers than in a subject working on an ergometer at constant wind velocity, and greater still in bad weather. On the other hand, there is some small gain outdoors from short-wave radiation even with overcast skies. The wetting effect was perhaps magnified in these experiments because of the rather low relative humidity. In natural conditions when rain is falling, evaporative cooling is less; but considerable amounts of water fall on the clothing and have to be warmed. For example, the volume of water falling on a surface 1 sq. m in area amounts to 10 l. for each centimetre of precipitation. In spite of these differences from natural conditions, the conclusion can safely be drawn that the overall insulation of a man's clothing, plus air, when he is wet through and exposed to a strong wind, will be extremely small—and probably of the order of 0·3 Clo—which is the insulation value of air alone at a lower wind velocity (for example, of 5 m.p.h.). He is therefore in the same situation *vis-à-vis* total insulation as if he were nude at the same ambient temperature but at somewhat lower wind velocity. (The distribution of skin temperatures in various body regions would, however, be different, the trunk being warmer and the limbs cooler than in the nude subject.)

The principal defect of the 'Four Inns Walk' clothing was the lack of insulation and protection from wind and wetting over the lower limbs. Even at rest in still air, skin temperatures over the legs and thighs were unduly low and accounted for the comparatively low mean skin temperatures. With wind and wetting, the skin temperatures over the lower limbs fell to 14° C, values at which rather severe muscle cooling would be expected at least in thin subjects[20,21]. This finding afforded a possible explanation for muscular weakness as an early symptom in exposure[16,22]. Further investigations of this aspect are being undertaken.

The evaluation of heat exchange. There are several uncertainties connected with the evaluation of heat exchanges by indirect calorimetry; among them are the estimation of evaporative heat loss and the evaluation of energy expenditure as mechanical work.

Evaporative heat loss. In clothing experiments a rather wide discrepancy may be observed between the change of nude weight and clothed weight over a given period of time, and this was the case in the present experiments. There are reasons for doubting whether either of these measurements gives an accurate estimate of evaporative heat loss from the skin in cool conditions. We have therefore used Belding's estimate of 6 kcal/m² h for evaporative heat loss from the skin in clothed subjects[3], and calculated respiratory heat loss from the measured volume of ventilation rather than attempting to calculate evaporative heat loss from weight changes. The second uncertainty in the evaluation of heat exchange is the estimation of energy expenditure as mechanical work. In bicycle ergometry we multiply the work performed by 1/427 to obtain its thermal equivalent and deduct this value from metabolism in calculating metabolic heat production. A similar procedure may be used to evaluate heat production in persons walking uphill, in which case one deducts from metabolism the thermal equivalent of the work done in lifting the body. On the other hand, in persons walking on the level, energy expenditure as external work is negligible[23]; and in going downhill there may well be heat gain from dissipation of potential energy. No direct measurements of the latter have yet been made,

although the energy cost of so-called 'negative' work has been a subject of interest to physiologists for many years.

In hill walkers, variation in mechanical work associated with changing terrain appears to be more or less balanced by variation in the rate of progress and therefore of oxygen intake. Consequently, metabolic heat production may remain reasonably uniform in spite of variation in oxygen intake. In recent observations on hill walkers, the oxygen intake of men walking at their natural pace was 2·5 l./min on ascents, 2·0 l./min on horizontal ground and 1·5 l./min on descents. If one deducts or adds 20 per cent for mechanical work during ascent and descent, respectively, the heat production for uphill, downhill and level sections seems to be much the same, that is, about $2 \times 5 \times 60 = 600$ kcal/h.

Fatigue and exposure. Although these experiments were conducted primarily for the purpose of determining Clo values, the results are also of interest in connexion with the physiology of hypothermia. The striking elevation of metabolism during standard exercise under cold stress affords a possible explanation of the early onset of fatigue in exposure casualties. A similar finding was reported by Adolph and Molnar[8]. Results such as these suggest that within certain limits metabolism rises to a level necessary to maintain thermal balance and that this may be achieved (*a*) by increasing the work-rate, (*b*) by shivering, or (*c*) by other unexplained means. In severe cold stress the metabolic demand may be so high that only very fit persons can meet it over a prolonged period.

A quantitative approach to this subject has been attempted in Fig. 2 by treating the tissues, the clothing and the air as thermal resistors in series along the pathway of heat flow from the central body mass to the surroundings[4], thus:

$$\frac{T_A - T_R}{H} = I_A + I_{Cl} + I_T = \Sigma I \qquad (6)$$

A difficulty arises from the fact that evaporative heat loss from the skin is deducted from metabolism in calculating I_{Cl}, but not in the calculation of I_T. However, for cold conditions evaporative heat loss from the skin is small and H can be taken as being equal to metabolism minus respiratory heat loss so that $H = 0{\cdot}9$ M. Fig. 2 shows the relation of $R_R - T_A$ to metabolism for various values of ΣI.

The chart can be used to predict the final value of rectal temperature for any given combination of ambient temperature, wind velocity, clothing insulation, tissue insulation and metabolism.

The following examples will serve to illustrate the method of calculation: From the results in Table 2 and Table 1*b*, I_{Cl} for wet clothing = 0·17 Clo, I_T during exercise = 0·51 Clo and I_A for gale force wind = 0·10 Clo, so that $\Sigma I = 0{\cdot}78$ Clo. At an ambient temperature of 0° C and oxygen intake of 1·5 l./min, the equilibrium value of T_R is 28·5° C and hypothermia would be inevitable. On the other hand, if mean oxygen intake is 2·0 l./min, the T_R at thermal equilibrium will be 37·9° C.

For a person in wet clothing who is sheltering from the wind at 0° C, $I_{Cl} = 0{\cdot}5$ Clo, $I_T = 0{\cdot}8$ Clo (in thin subjects I_T may be as low as 0·55 Clo at rest and 0·35 Clo during exercise), and $I_A = 0{\cdot}4$ Clo, so that $\Sigma I = 1{\cdot}7$ Clo. In order to prevent a rectal temperature falling below 37° C, oxygen intake must be 0·9 l./min or 3·6 times basal. Whether or not a person can manage this over a long period will depend to a large extent on whether or not he was exhausted on taking shelter. On the other hand, in dry clothing with waterproof over-garments, I_{Cl} will be 1·5 Clo and ΣI will be 2·7 Clo and oxygen intake need be only 0·56 l./min or twice basal.

The chart also brings out the fact that the effect of clothing and tissue insulation on rectal temperature is larger at high than at low metabolism; this means that relatively small variations in I_{Cl} or I_T become important at high rates of metabolism. For the same reason a person with average subcutaneous fat may be able to maintain a normal rectal temperature at a work-rate which will cause an unusually thin person's rectal temperature to fall dangerously low. Thus for the subject of these experiments ΣI for wet clothing and gale-force wind would be 0·78 Clo during exercise, and with oxygen intake of 2 l./min and ambient temperature of 0° C, he would have a T_R of 37·8° C. For a thinner person with ΣI of 0·68 Clo, the corresponding T_R would be 33·0° C.

Now in order to maintain his rectal temperature at 37° C the thin subject would need to raise his oxygen intake to 2·24 l./min, which is an increase of 12 per cent. Such an increase is small compared with the sixteen-fold possible range between basal and maximal oxygen intake. On the other hand, the associated 12 per cent increase in $T_R - T_A$, when $T_A = 0°$ C, amounts to $37 - 4 = 33°$ C, which is the difference between normality and incipient hypothermia. Thus apparently trivial differences in metabolism or total insulation can have disastrous consequences in the wet cold situation, in which exposure casualties commonly occur.

Thus in summary:

(1) The thermal insulation value of clothing worn in the 'Four Inns Walk 1964' (ref. 1) was 1·5 Clo units, which may be compared with 1·0 Clo for business clothing[4] and 3·0 Clo for polar clothing assemblies[5,6].

(2) The effects of exercise, wind and wetting on clothing insulation were studied. When the subject exercised in wet clothing in a 9-m.p.h. wind, clothing insulation fell to 0·17 Clo, which was 15 per cent of the control value for dry clothing in still air with the subject at rest.

(3) The thermal insulation of the body tissues was also determined and it was shown how apparently small changes in oxygen intake and insulation can have disas-

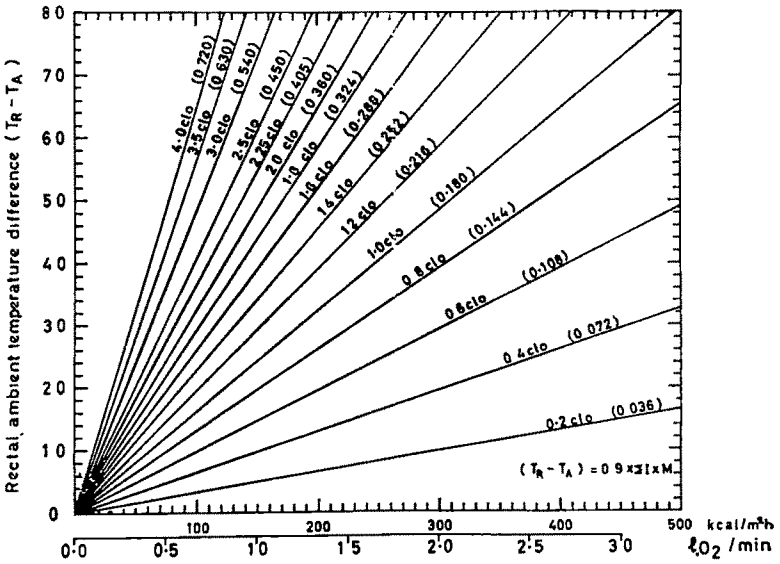

Fig. 2. Chart for predicting final body temperature (R) under given conditions of ambient temperature, total thermal insulation and metabolism. Ordinate shows difference between rectal and ambient air temperature ($T_R - T_A$) in ° C, abscissa shows metabolism in kcal/m² surface area/h and oxygen consumption for an average man of 75 kg weight and 2 m² surface area. The values of total insulation (ΣI) are given in Clo units with c.g.s. units in parentheses. $\Sigma I = I_A + I_{Cl} + I_T$. The equation of the graphs is $(T_R - T_A) = 0{\cdot}9 \times M \times \Sigma I$, ΣI being expressed in c.g.s. units. To convert Clo to c.g.s. units, multiply by 0·18

trous effects on body temperature under conditions of severe cold stress.

OBITUARIES

Prof. Saul Adler, O.B.E., F.R.S.

Saul Aaron Adler died in Jerusalem on January 25, 1966, at the age of 70. He was the leading Jewish parasitologist of this century, yet so modest that he was always astonished when honours came his way, or at the crowds which gathered to welcome him at airports on his frequent journeys throughout the world.

Adler was born in the town of Karelitz in Russia in 1895, and five years later was taken to England where the family settled in Leeds. He went to school there and qualified in medicine during the First World War at the University of Leeds, at this time showing no clear signs of the brilliant future which lay ahead. Soon after taking his degree, he joined the Royal Army Medical Corps and served in the Middle East, which gave him his first taste of tropical medicine. It was natural, therefore, that on demobilization he should take the Diploma in Tropical Medicine of the University of Liverpool and join the staff of the Liverpool School. He went out to the Sir Alfred Lewis Jones Research Laboratory at Freetown in West Africa, and became immersed in the study of the parasites in the local inhabitants and animals. He was under the guidance of Profs. Blacklock and Gordon, and he realized the debt he owed them until the end of his life. In 1923, he married Sophie Husden of similar Russian Jewish extraction to his own, and they had two sons and a daughter, all of whom survive him. In 1924, he was called to Jerusalem by Chaim Weizman, at that time president of the Jewish Agency for Palestine, in order to develop the new Institute of Microbiology. He was soon appointed professor and was associated with the Hebrew University for the remainder of his life.

Adler's researches led him, however, far afield; his main subject of interest was leishmaniasis, in all its forms, and at every stage of its life-history. He investigated the disease around the Mediterranean basin and far into the Middle East; and, in later life, in East Africa, China, Brazil and Panama. In every phase of his investigations, he tried to start with the basic elements. Thus, a good experimental host for the parasite was lacking, so he sought a suitable animal, and found one in the golden hamster in the desert near Aleppo. He colonized it in his institute and, with typical generosity, distributed the progeny to laboratories everywhere. The invertebrate host of *Leishmania* was unknown when Adler began his research, although species of *Phlebotomus* were suspected. With O. Theodor, he made a profound study of these insects, beginning with the anatomy and physiology of their mouth parts and alimentary tract, continuing with observations on the behaviour of cultures of the parasites in the gut and their exit through the proboscis in the act of biting, and, finally, demonstrating transmission of *L. tropica* to volunteers by experimentally infected sandflies. From the experimental host, and the invertebrate vector, Adler passed to work on the parasite itself, and he became convinced, after a lifetime of observations, of the multiplicity of species which exist in the genus *Leishmania*. Biological and clinical features of the disease had at first led him to this opinion, which, in the final years of his life, he was able to confirm by a serological reaction, the technique of which he demonstrated to students in Israel, Britain, Italy, Brazil and elsewhere, realizing that he had not much time left for establishing the unique usefulness of this test.

A leishmanial stage in the course of the life-cycle of *Trypanosoma cruzi*, the cause of Chagas's disease, naturally aroused the interest of Adler and, on visits to Brazil, he became well acquainted with this infection. The disease, however, had another attraction for him, because his second great interest was Darwin and evolution; he had studied Darwin's life and works in the greatest of detail (translating his *Origin of Species* into Hebrew), and, in 1959, he put forward the hypothesis that Darwin suffered and died from Chagas's disease. He showed that Darwin must almost inevitably have become infected with *T. cruzi* on landing in a highly endemic area of South America in 1835 and that the chronic invalidism, including angina, which followed was characteristic of the cardiac form of Chagas's disease. Adler applied the subject of evolution to protozoa, and showed the operation of its laws not only in the species complex of *Leishmania*, but also in *Trichomonas*, insect crithidia, and in rodent malaria parasites.

Malaria was another subject on which Adler's original mind cast light. His first researches in West Africa were devoted to species of *Plasmodium* present in the local chimpanzees and lizards, and it was during his sojourn in Sierra Leone that he first used himself as a human volunteer, attempting without success to pass the parasites of the chimpanzee to man. He never ceased to carry out such experiments, which were more successful in leishmaniasis and relapsing fever; in fact, an infection of the latter nearly killed him. From work on the parasites of apes, Adler changed in the later years of his life to a study of the plasmodia of rodents, and produced interesting adaptations of *P. vinckei* in hamsters. He was convinced that this field in general offered possibilities of great promise to the geneticist.

Adler was the recipient of many honours; he most prized his election as a Fellow of the Royal Society in 1957; he appreciated the award of O.B.E. from his 'second' country, Great Britain, in 1946, and of the Israel Prize for Medical Science on his deathbed in Jerusalem. Other honours included the Laveran Medal, the Gaspar Vianna Medal, the Chalmers Medal of the Royal Society of Tropical Medicine and Hygiene, the Order of the Cross of the Phoenix of Greece, and the honorary degree of doctor of science conferred on him by the University of Leeds in 1965. Adler's life was too short to enable him to carry out everything he would have liked to do. He had still much research before him in parasitology; like his father, he was a Hebrew scholar and wished to work on the Dead Sea

Scrolls; he could have made his name in pure mathematics, chess or literature. Adler created a school of ardent followers in Israel; his influence was scarcely less in many other parts of the world, where his many friends and students deplore his passing. P. C. C. GARNHAM

Dr. Maurice N. Hill, F.R.S.

THE sudden death at Cambridge of Maurice Hill, on January 11, 1966, at the age of 46, has made the lives of many people the poorer. It is difficult to think where he will most be missed, so wide were his interests: whether it was as research scientist, supervisor of research students, devoted college man, tireless member of committees, or simply as a warm, lovable family man that he made most impact, is a question that fortunately does not need answering. However, it is certain that it was his warmth that was the key to everything.

He was born on May 29, 1919, son of Prof. A. V. Hill, and, after schooling at Highgate, set out on an undergraduate career at King's College, Cambridge, in 1938, which was interrupted by the Second World War. He left Cambridge in 1939 and was assigned to the Anti-Submarine Establishment at Portland; later he moved to the Establishment at Edinburgh that was developing methods of sweeping magnetic and acoustic mines. Here he made many friends, including Ben Browne, Edward Bullard, Leslie Flavill and Tom Gaskell, with whom much of his later work was done.

When the War ended, Hill had definite plans to carry out research into marine geophysics at Cambridge, but he had first to complete his undergraduate training. He had married Philippa Pass in 1944 and, having now a son, he took his degree as soon as possible, to move into the less restrictive world of academic research. He was to stay with the Department of Geophysics at Cambridge for the rest of his life. His Ph.D. was on the subject of marine seismic prospecting. It was a notable dissertation—he had developed a new technique of geophysical exploration and it was soon to become the most valuable tool available to marine geophysicists.

In 1949 he became an assistant in research and from that time he was able to devote himself fully to elucidating the nature of the Earth's crust and upper mantle beneath oceans; it was soon realized that the relative thinness of the oceanic crust in comparison with the continental crust enabled us to learn much about the forces and processes at work in the mantle, and Hill ensured that British contributions to knowledge about ocean basins and what lay beneath were of high standard. The *Challenger* Expedition of 1950–53, which he helped to organize, was a spectacular example of this, but there were many other expeditions to specific oceanic features by means of which Hill, with his colleagues, gradually got the 'feel' of sub-oceanic geology.

Instruments for this purpose steadily developed—the precision echo-sounder, the towed magnetometer, the sea gravimeter, heat flow apparatus, improved corers, long-range seismic apparatus, ocean bottom seismometers, a reflexion seismic profiler and a deep diving magnetometer. Hill was responsible for the evolution of many of these, and he and his growing number of research students put them to intensive use.

It could well be said that 1963 was an *annus mirabilis* for Hill. Apart from being chief scientist on R.R.S. *Discovery* during the highly successful geophysical ventures in the Indian Ocean, he also saw published, under his editorship, *The Sea*—three very comprehensive volumes on physical and chemical oceanography and the underlying rocks.

Apart from his continued assault on the Atlantic Ocean, in recent years he was much concerned to improve sea-going facilities for university research departments—he was largely instrumental in the conversion of a ship for university use; this will come into service later this year.

He became a Fellow of King's College in 1949 and during 1961–65 was director of studies in natural sciences there. In 1954 he was made assistant director of research in the Department of Geophysics and in 1965 became reader in marine geophysics. He was elected a Fellow of the Royal Society in 1962, and, in 1963, was awarded the Charles Chree Medal and Award of the Physical Society.

And yet, effective scientist that Hill was, it was his humanity that left an indelible impression. The practical side of sea-going places greater demands on a scientist than mere intellectual distinction and cleverness. An apparently paradoxical combination of the rugged and gentle is necessary, as is more than average common sense and a deep understanding of people. All these he possessed in great measure. It goes without saying that he was an admirable supervisor of research students to whose problems, scientific and otherwise, he was always responsive. Not for him the occasional formal interview with his students—they used to occupy him full time, and he would not have had it otherwise. He was aware that the strength of a science lies in a steady inflow of young research workers, and their well-being and happiness are of fundamental importance. To Maurice, the human element of science—the encouragement, sympathy, support, and even just the attentive ear—was uppermost.

One aspect of his life that was characteristic and which extended beyond the bounds of science was his generosity. He and his wife were deeply concerned with the problems of anyone in need. It is impossible to guess how much charitable work he did—most of it was never revealed—but his giving was both munificent and imaginative.

He was a man of many aspects, all of them genial. He will be remembered with affection far beyond the scientific community. D. DAVIES

NEWS and VIEWS

Experimental Pharmacology in the University of Strathclyde: Prof. W. C. Bowman

DR. W. C. BOWMAN, at present reader in pharmacology in the School of Pharmacy, University of London, has been appointed to a professorship in experimental pharmacology in the University of Strathclyde. Dr. Bowman was a student, research student and lecturer at the School of Pharmacy. After qualification he worked with Dr. (now Prof.) E. J. Zaimis on neuromuscular transmission. He has been interested in the mechanism of action of neuromuscular blocking agents. Working with Dr. M. J. Rand, he found that triethylcholine produced a temporary effect in the cat and rabbit which closely resembled that seen in man in the case of the syndrome myasthenia gravis. He found that triethylcholine had a prejunctional site of action and suggested that the compound might be of use in the treatment of neurogenic spastic states. More recently he has been interested in the effect of adrenaline in potentiating the contraction of skeletal muscle and has investigated the effect of sympathomimetic amines on both innervated and chronically denervated skeletal muscles. Bowman has contributed a great deal towards the success of pharmacology at the School of Pharmacy, both as a teacher of undergraduates and of postgraduates. He has proved a most lucid and

stimulating teacher and has enabled many students to achieve success in this subject. He has published many papers and has given communications and demonstrations to societies both in Britain and in the United States. He has become an international authority on this work. Dr. Bowman will take up his post at the University of Strathclyde on September 1.

American Association for the Advancement of Science

Dean Don K. Price, jun., assumed office as president-elect of the American Association for the Advancement of Science on January 15. He is one of the few social scientists to hold this office, the most recent being the economist, W. C. Mitchell, in 1938. Since 1958 Don Price has been Dean of the Graduate School of Public Administration of Harvard University, and has the broad background necessary to guide the association, the wide objects of which are "to further the work of scientists, to facilitate co-operation among them, to improve the effectiveness of science in the promotion of human welfare . . .". Don Price was a Rhodes scholar at Oxford from 1932 to 1935.

Aid to India

In reply to a question in the House of Commons on February 17, the Prime Minister, Mr. H. Wilson, said that the Governments of the United Kingdom, Canada, Australia and New Zealand, and of some non-Commonwealth countries, were already in close touch with each other and with the Government of India regarding the threatened famine in India. Britain had made an immediate and interim contribution in the form of an interest-free loan to India of £7·5 million. The Australian Government on February 17 announced a very large shipment of food to India, and the problem was, above all, one of port capacity and internal distribution; some very massive shipments of food were being organized. Replying for the Prime Minister on February 24, Mr. G. Brown added that the Government was in touch with the Indian Government about supplies of food which could be made available if they were needed. Discussions about further aid were still in progress.

Anglo-French Co-operation in Oceanography

In reply to a question in the House of Commons on March 3, the Minister of State for the Department of Education and Science, Mr. R. E. Prentice, said that details of the French Government's intentions for undersea research had not been made known to the British Government, but there had been unofficial exchanges between scientific organizations in the two countries, and the Secretary of State was prepared to consider any proposals that might be made. British oceanographers and geographers at research establishments of the Natural Environment Research Council and at universities had co-operated with French scientists in such research and would continue to do so. The Natural Environment Research Council was at present reviewing the future orientation of oceanographic research in Britain. Both Britain and France, along with other countries, were represented on the Inter-Governmental Oceanographic Commission.

Research in Mental Health

The debate in the House of Commons on February 18 on Mr. W. Hamling's motion to transfer responsibility for the education and training of all mentally handicapped children from the Ministry of Health to the Department of Education and Science was noteworthy for the repeated reference to the need for more research in this field. Sir David Renton, commenting on the unevenness of scientific and social advance, pointed out that the great progress in antibiotic therapy had intensified the problem of dealing with the mentally handicapped. Progress in detecting, preventing, and curing mental defects did not match the advances in antibiotics and obstetrics and there was immense scope for further research. Dr. E. Summerskill also referred to the growing magnitude of the problem and advocated the establishment of an Educational Research Council. At present, only about twelve people in Britain were investigating the learning processes of severely sub-normal children, though Dame Joan Vickers paid tribute to the quality of some of this work. She herself suggested that the Ministries of Education, Health and Labour should set up an interdepartmental committee to review the scale of the problem. Mr. J. Snow was concerned at the disparity between the scale of mental health research and the administrative action of the Ministry of Health in this field. He urged that more attention be paid to the problem of the autistic child. Lord Balniel strongly urged more support of research into the learning processes of backward children and referred to the work now in progress at the University of Manchester. Mr. L. Pavitt fully supported those who urged more research into the problems of the mentally handicapped, as did Mr. A. Mackenzie and Sir Edward Boyle, who added that the limiting factor to-day was the supply of trained workers for such research. On the proposed transfer of responsibility from the Ministry of Health to the Department of Education and Science, Sir Edward, like numerous other speakers, had reservations, while welcoming the motion generally. The Parliamentary Secretary to the Ministry of Health, Mr. C. Loughlin, replying on the debate, warmly welcomed the pleas for more research into mental health generally and promised to see that research was as far as possible extended, but he had reservations on the proposed transfer of responsibility, and the resolution was, by leave, withdrawn.

Durban Museum and Art Gallery

The director of the Durban Museum and Art Gallery reports that during 1964–65 the Department of Local History was moved from the Old House to the refurnished Old Court House (*Annual Report of the Durban Museum and Art Gallery for the Municipal Year 1964–1965*. Pp. 18. Durban: Durban Museum and Art Gallery, 1965). The Old House was later altered and redecorated and will shortly be opened as a period house. Work on the displays in the Museum was devoted to the installation of the new geological exhibits and much time was spent in planning the rearrangement of the Hall of South African Birds. Collecting trips included one to Northern Natal and another to the eastern area of Cape Province.

Oil and Gas Pipelines in Europe

The network of large pipeline systems established in Europe for the transportation of crude petroleum, refined products, and gas, has now reached an advanced stage in development, which has so far taken only about 12 years to realize. During this comparatively short period, some 1,700 miles of large diameter crude oil pipelines have been built in various systems, delivering more than 70 million tons of crude oil per annum to European refineries. Such are the projects now planned, some well under way, that within the next 2 years more than 500 miles of pipeline, capable of delivering a further 50 million tons of crude oil to Central Europe each year, will, it is anticipated, be completed. Implicit in this vast network are a number of 'products pipelines' designed for the speedy transference of a full range of refined petroleum products, including fuel oil, from strategically placed refineries to the major centres of consumption, and many more such lines are already being planned. In addition, the gas industry has already completed many hundreds of miles of high-pressure gas distribution pipelines; one result of this is to make obsolete the many small individual gas-producing plants that previously existed.

Among the most ambitious of these European oil pipelines is undoubtedly the Trans-Alpine Pipeline (commonly known as TAL), from Trieste, at the head of the Adriatic, to Ingolstadt in South Germany, the centre of a large refinery complex; some details of this venture have already been recorded in these columns (*Nature*, **208**, 435; 1965). The largest pipeline at present operating in Europe, completed in 1962, runs 782 km from L'Avera on the Mediterranean, northwards to feed refineries in Strasbourg, Karlsruhe and Mannheim. This pipeline is sponsored by the Société Du Pipe-Line Sud Européen (SPLSE), a consortium of major oil companies operating in France and Western Germany (including Compagnie Française des Pétroles—a French Government concern); by means of another system (Rhine Donau Oelleitung, RDO), supplies are fed to other refineries in Bavaria. Other notable lines are from Ludwigshafen to Wilhelmshaven (Nord West Oelleitung, NWO); also the Central European (CEL) system serving Italy, Switzerland and Southern Germany. An informative article, with a good explanatory map of locations of existing and projected pipelines and refineries, by R. E. Watkins, is included in what is, most regrettably, the last issue of *BP Magazine* (British Petroleum Company, London. No. 18; winter 1965). This magazine first appeared in 1960 and it has consistently set a remarkably high standard in design, illustration and presentation of subject-matter.

The San Mateo–Hayward Bridge, California

A NEW bridge of unusual design is under construction which will eventually carry four to six lanes of traffic across the southern part of San Francisco Bay, California, when it is completed in 1967. This bridge will incorporate nearly a mile of orthotropic spans in its 7-mile length. In this particular orthotropic design, the deck carries most of its own weight and this eliminates the need for the overhead steel supports and cables common to conventional steel bridges. Use is made of new high-strength steels, pressed into corrugated form; the resulting ribs possess enough strength to enable the deck to be self-supporting over spans of up to 750 ft, the length of the central span in this new bridge. It is claimed that the orthotropic design for bridges offers advantages both in economy and speed of construction. A similar bridge has already been completed from Montreal to an island in the St. Lawrence River, the site of the 1967 World Exhibition. According to an article entitled "A Big Order" (*The Lamp*, Standard Oil Company (New Jersey), New York, **47**, 1965), all supporting towers of the San Mateo Bridge will be aluminium in colour, the body of the bridge being in gold. A remarkable ancillary feature of this construction is the very large quantity of the protective coatings required for coating the steel of the structure. The Humble Oil and Refining Company (a subsidiary of Standard Oil Company (New Jersey)) is scheduled to supply 25,000 gallons of undercoat ('Rust-Ban 191') and 125,000 gallons of vinyl-based top-coat to protect all the steel. These protective coatings are being applied to the prefabricated steel sections in a specially constructed building 15 miles away from the site, to which the sections are afterwards transported by barge.

Syntex Corporation of America

THE Syntex Corporation is internationally known for its pioneer research activities and manufactured products in the pharmaceutical industry. It operates through various marketing subsidiaries, of which, in the United States, Syntex Laboratories, Inc., with administrative and research centres at Palo Alto, California, is the principal. Other subsidiaries are located in Mexico (Syntex, S.A.), in Canada (Syntex, Ltd.), while in England the group has now established its own marketing organization to cover Great Britain and most Commonwealth countries. To accelerate the dissemination of medical and marketing information to distributors of Syntex products, new regional offices have been opened in London, Madrid and Milan, to augment the work of the centre previously established in Zurich. Among the distributors of Syntex products are such well-known firms as Imperial Chemical Industries, Ltd. (United Kingdom); Laboratories Cassenne (France); Chemie Gruenenthal GmbH (West Germany, Austria and Switzerland); Instituto Farmacológico Latino, S.A. (Spain); Recordati Laboratorio Farmacologico S.p.A. (Italy); and Tanabe Seiyaku Co., Ltd. (Japan). According to the *Annual Report of the Syntex Corporation for the Fiscal Year ending July 31, 1965* (Pp. 24. Panama: Syntex Corporation, 1965), substantially increased sales resulted in net earnings of more than 10 million dollars, the highest in the history of the Corporation. Sales for the United States market constituted 46 per cent of total sales in the fiscal year 1965, Europe accounted for 29 per cent, Latin America for 14 per cent, and other countries 11 per cent. Of the drugs and other products with which Syntex is concerned may be mentioned steroids for treatment of inflammatory diseases, including the 'Synalar' group comprising compounds for treatment of skin conditions; drugs used in the area of reproductive physiology, consisting primarily of several oral contraceptives; steroid intermediates, and finished sex hormones. Animal health products feature strongly in another category of Syntex manufacture. During the year under review, a new form of 'Synalar' (fluocinolone acetonide) was introduced to veterinarians in the United States designed for animal therapy. This was followed by the drug 'Flucort' (flumethasone), a new anti-inflammatory corticoid used in treating various rheumatic, allergic and metabolic disease conditions in large and small animals.

The California Bearing Ratio Test on Loess

THE California bearing ratio test, one of the mainstays of soil mechanics and conventionally popular with civil engineers, especially when concerned with highway and aerodrome runway construction, has undergone some critical modifications both in technique and interpretation, since O. J. Porter first described his original methods in two papers, "The Preparation of Subgrades" and "Foundations for Flexible Pavements" (*Proc. U.S. Highways Res. Board*, **18**, Part 2, 1938; and **22**, 1942, respectively). Porter's original text was essentially a soil classification test, as we know it to-day. With the advent of the Second World War, the U.S. Corps of Engineers had to build many aerodromes and access roads under many different subgrade conditions, often in a very short space of time. From various flexible pavement design methods the California bearing ratio test was selected, and after a thorough examination of its merits and applications, the U.S. Corps of Engineers made some important changes in Porter's original procedures. These were, briefly, the use of dynamic compaction instead of static compaction; the compaction of soil to dry density and the use of the moisture content expected during compaction in the field (thus the test became a measure of soil shear-strength, not just a classification test); a correction was also introduced for California bearing ratio load-penetration curves (initially concave-upwards). After 1945, the test was universally adopted in highway construction work. In Britain, however, further amendments were made, such as dispensing with soaking procedure, and reversion to static compaction. It is clear from a timely paper by J. P. Blakeley entitled *The California Bearing Ratio Test on Loess* (National Roads Board: Road Research Unit. Bulletin No. 2. Pp. 18. Wellington, New Zealand, 1965) that further modifications of this test are both desirable and imminent. As he points out, the trend towards the use of bound base-courses and stiffer surfacings is causing difficulty in the application of the California bearing ratio test, and this method of pavement design will have to be modified to make rational allowance

for the all-important load-spreading properties of the pavement. The author divides his paper into two parts. The first part consists of a review of the California bearing ratio test, and the second deals with relationships between soil dry density, compaction moisture content and soaked/unsoaked bearing ratio. The first part is an objective survey of the California bearing ratio test past and present. The second gives the results of considerable experimentation in terms of its title, conducted on one soil only, Heathcote Loess; but he finds that trends in the variation of bearing ratio values with moisture content and density should be true of a variety of soils.

A Virus Disease in Crustacea

Prof. C. Vago, of the Laboratoire de Cytopathologie, Saint-Christol-les-Alès, has written to the Editor reporting the incidence of a virus disease in a crustacean. The virus diseases so far described in invertebrates have been either from insects or from Acaria. The present virus was observed in *Macropipus depurator* L. (*Portunus depurator*). Diseased animals collected on the French 'Languedoc' coast of the Mediterranean showed a slow development of paralysis; sometimes a slight darkening was observed at later phases of the disease. Inoculation of blood from diseased animals into healthy ones provoked these symptoms. An infectious fraction was obtained from the suspension of homogenized muscle, heart and gland tissue by filtering them through 450-mμ 'Millipore' membranes and by alternate centrifugation at a maximum of 30,000 r.p.m. An electron microscopic study of this fraction, after negative staining with phosphotungstic acid, revealed numerous paraspherical virus bodies, 50–60 mμ in diameter (Fig. 1). The same viruses were also obtained from the tissue suspension by purification with trichlorotrifluorethane. Histological investigations of infected tissues and further analysis of the virus are in progress.

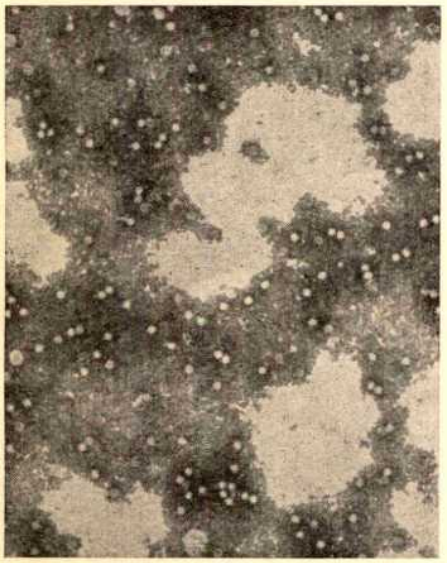

Fig. 1. Virus bodies isolated from paralysed *Portunus depurator*. Negative staining with phosphotungstic acid (×30,000)

Hot Springs and Fumaroles at Jebel Marra, Sudan

D. Hammerton, of the Hydrobiological Research Unit, Faculty of Science, University of Khartoum, has written to the Editor as follows: "The volcano of Jebel Marra (3,024 m. latitude 24° 16′ E., longitude 12° 58′ N.) in Darfur Province, Sudan, has hitherto been regarded as extinct. It consists of a well-developed caldera 3 miles in diameter with a central cone containing a deep crater lake. A larger, shallow lake occupies part of the eastern floor of the caldera. While engaged on a biological investigation of the two lakes in January, 1966, I made two discoveries which suggest that the volcano must be regarded as dormant. First, a series of hot springs, ranging in temperature from 65°–85° C, were found along the north-west margin of the inner crater lake. The volume of flow is probably greater than can be accounted for by precipitation and it is suggested that the springs consist either of juvenile water or of water which leaks through the floor of the lake and is subsequently heated and forced to the surface. Secondly, exploration of the outer north-west slopes of the inner crater revealed the presence of a valley in which there are numerous fumaroles emitting hot gases under pressure. The whole valley was filled with a strong smell of sulphur dioxide, and numerous dead birds and insects were observed in the vicinity of each fumarole. Three adjacent valleys, though not explored in detail, appeared to contain similar fumaroles. This record of fumarolic and hot spring activity is of considerable vulcanological interest in Africa because of the northerly position of the volcano. Detailed chemical analyses have been made of the waters of the lakes and of the hot springs in conjunction with biological studies, and the results will be published elsewhere."

Research Facilities at Naples, Plymouth and Windermere

How many workers in the biological sciences to-day are aware of the research facilities available at the Biological Stations at Plymouth and Windermere and the Naples Zoological Station? The British Association for the Advancement of Science was actively concerned in the foundation of all three of these Stations, and its continuous financial and moral support has entitled it to table space and the use of research equipment and other material at the Stations. The opportunity to use these facilities—in some respects unique—is open to teachers, senior students and research workers in universities, university colleges and other educational or research establishments who apply to the British Association. There is no limit to the time available to applicants at the Marine Biological Station, Plymouth, and the Freshwater Biological Station, Windermere; but at the Zoological Station, Naples, the Association is entitled to only one month's table space during any twelve months running from July 1 to the following June 30, and for administrative reasons applications should be submitted as long in advance as possible. Successful applicants in all cases will be offered a place, free of charge, in the laboratory in question, and the use of the equipment and material necessary for carrying out the programme of work involved. Applications should be addressed to the Secretary, British Association for the Advancement of Science, 3 Sanctuary Buildings, 20 Great Smith Street, London, S.W.1, and should include a statement of qualifications, the work in which it is desired to engage, and the dates for which the use of table space is required. Applications will be submitted to a committee of the Association (and in the case of the Naples Station to a Committee of the Royal Society) for approval.

Scientific Research in France

An article in *Le Progrès Scientifique* (No. 91, December 1965) analyses expenditure on research and development in France in 1963. Public expenditure was 4,508 million francs, of which 110 million francs was for space research and 1,453 million francs for military research. A further 2,073 million francs was expended by private enterprise on industrial research, about 18·7 million francs by non-profit institutions and about 82·9 million francs was provided by international organizations, making a total of 6,249 million francs. Of this total, 2,267·5 million francs was spent in the State sector, 844·1 million francs in the educational sector, 3,103 million francs in the industrial sector, and 34·2 million francs by non-profit institutions;

3,347 million francs was spent on research and 2,901 million francs on development.

Scientists in Mexico

PART I (*A–G*) of the volume on Mexico in the series *Scientific Institutions and Scientists in Latin America*, issued by the Centre for Scientific Co-operation in Latin America of the United Nations Educational, Scientific and Cultural Organization and the Organization of American States, contains the information regarding scientists in Mexico which was contained in the earlier three volumes issued in 1951, and in 1955 brought up to date and with many new references (Pp. 372. Montevideo, 1965).

Royal Geographical Society: Awards

THE Royal Geographical Society has announced the following medals and awards for 1966: *Patron's Medal*, Prof. E. J. H. Corner, leader, Royal Society Expeditions to North Borneo and the Solomon Islands; *Founder's Medal*, G. Hattersley-Smith, for glaciological investigations in the Canadian Arctic; *Victoria Medal*, G. R. Crone, librarian and map curator, Royal Geographical Society; *Murchison Grant*, Prof. S. G. Davis, University of Hong Kong; *Back Grant*, Dr. S. Evans, Scott Polar Research Institute, Cambridge; *Cuthbert Peek Grant*, Lieut. Commander M. K. Burley, leader, Combined Services Expedition to South Georgia; *Gill Memorial*, P. Haggett, University of Cambridge; *Mrs. Patrick Ness Award*, E. C. Evans and J. P. M. Long, Welfare Branch, Northern Territory Administration, Government of Australia.

University News: Belfast

DR. K. J. IVIN, at present reader in physical chemistry in the University of Leeds, has been appointed to the chair of physical chemistry.

Bradford Institute of Technology

DR. A. BOTTOMLEY, at present Ford Foundation adviser to the Institute of Public Administration and Development of the Lebanese Government, has been appointed professor of economics. Dr. W. R. A. D. Moore, reader in high polymer chemistry at the Institute, has been appointed professor of polymer science.

London

PROF. A. C. OFFORD, at present professor of mathematics at Birkbeck College, has been appointed to the chair of mathematics at the London School of Economics and Political Science. Dr. G. R. Davis, resident mining consultant in Northern Rhodesia to the British South Africa Co., has been appointed to the chair of mining geology tenable at the Imperial College of Science and Technology. Dr. P. J. Grant, at present reader in engineering science at the Imperial College of Science and Technology, has been appointed to the chair of nuclear power tenable at that College.

Announcements

DR. N. P. ALLEN and Dr. O. Simpson have been appointed deputy directors at the National Physical Laboratory as from April 1. Dr. Allen, who joined the National Physical Laboratory as superintendent of the Metallurgy Division in 1944, will become deputy director (A), and Dr. Simpson, who joined the Laboratory in 1963 as superintendent of the Basic Physics Division, will become deputy director (B).

THE sixteenth annual meeting of the Société de Chimie Physique will be held in Paris during May 31–June 3. Further information can be obtained from Prof. G. Emschwiller, Société de Chimie Physique, 10 rue Vauquelin, Paris 5.

A COURSE on "Life in the Past", arranged by the Joint Biology Committee, will be held in the University of London on May 21. Further information can be obtained from the Treasurer, Joint Biology Committee, 11*a* Lonsdale Gardens, Tunbridge Wells, Kent.

AN international symposium on "Electron Microscopy and Cytochemistry" will be held in Leiden during May 30–June 4. Further information can be obtained from the Secretariat of the Symposium, Laboratory for Electron Microscopy, 62 Wassenaarseweg, Leiden.

A REVIEW symposium on "Modern Applications of Thermoelectricity" will be held at the Welsh College of Advanced Technology during April 20–22. Further information can be obtained from the Organizer of Short Courses, Welsh College of Advanced Technology, Cathays Park, Cardiff.

A SYMPOSIUM on "Traffic Safety—a National Problem" will be held in Washington on April 28, during the second annual meeting of the National Academy of Engineering. Further information can be obtained from the Secretary, National Academy of Engineering, 2101 Constitution Avenue, Washington, D.C.

A CONVENTION on "Thermodynamics and Fluid Mechanics", arranged by the Thermodynamics and Fluid Mechanics Group of the Institution of Mechanical Engineers, will be held in Liverpool during April 13–15. Further information can be obtained from the Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London, S.W.1.

THE spring meeting of the Western States Section of the Combustion Institute will be held at the Denver Research Institute during April 25–26. The subjects under discussion will be: fire research; pyrolysis of solid fuels and oxidizers; high-pressure, condensed-phase reactions; metal combustion. Further information can be obtained from the Secretary, Western States Section, the Combustion Institute, 16902 Bollinger Drive, Pacific Palisades, California.

AN international symposium on "Generalized Networks", arranged by the Microwave Research Institute of the Polytechnic Institute of Brooklyn, in co-operation with the Institute of Electrical and Electronics Engineers, the Optical Society of America and the Society for Industrial and Applied Mathematics, will be held in New York City during April 12–14. Further information can be obtained from the Symposium Committee, Polytechnic Institute of Brooklyn, 333 Jay Street, Brooklyn, N.Y.

A SYMPOSIUM on "Advances in Polymer Characterization", organized under the auspices of the Manchester and District Advisory Council for Further Education, will be held in the University of Manchester during April 20–21. The programme will include sessions on: solution properties and the determination of molecular weight distributions; characterization of tacticity; properties of amorphous polymers; crystallinity and crystallization. Further information can be obtained from the Registrar, Manchester College of Science and Technology, Manchester.

THE fifth general meeting of the International Mineralogical Association will be held at Cambridge during August 30–September 3. The programme will include symposia on crystal growth with special reference to minerals or bonding forces in mineral structures and on pyroxenes and/or amphiboles, and an evening session on problems of the quantitative measurement of reflectivity in ore minerals. Further information can be obtained from the Local Secretary, International Mineralogical Association Meeting, Department of Mineralogy and Petrology, Downing Place, Cambridge.

EXTENDING THE USEFULNESS OF MATERIALS

THE Materials Science Club held the third of its 1965 series of technical meetings on December 14 and 15 at the Atomic Energy Research Establishment, Harwell (see *Nature*, 206, 335; 1965). The meeting was divided into three sessions: the first was devoted principally to recent advances and future prospects in diverse fields such as ferrous and non-ferrous metals, ceramics, concrete, glass, paper, plastics and graphite. The second session covered general trends of development in materials science with particular emphasis on the inter-relationship between different fields. After a brief introduction covering the economics of new materials development, the final session was devoted almost entirely to a general discussion of the topics already covered during the meeting.

Recent advances in particular fields. The first material, graphite, was surveyed by Prof. A. J. Kennedy (the College of Aeronautics, Cranfield). Conventional polycrystalline graphites form a range of very varied materials the properties of which depend strongly on the origin of the cokes used as starting materials. The methods of preparation and purification of graphite can also profoundly affect the properties, as can be seen from the increase in density. That of conventional graphite lies in the range 1·5–1·9 g/ml.^{3}, recrystallized material is raised to 2·1, and the highly oriented pyrolytic form (deposited from the vapour phase) has a value of 2·2. The highest figure, that for a single crystal of graphite, is 2·26.

In principle, graphite is an outstanding material for high-temperature applications (with strength increasing to a maximum at about 2,700° C), and much effort has been devoted to developing new forms which might pay dividends in this respect. Graphites are characterized by a relatively high porosity—20–30 per cent is typical—and it is possible to achieve an improvement in mechanical and thermal properties by such techniques in impregnation and hot working.

The pyrolytic graphites are highly anisotropic, a feature which has both limitations and advantages. The fact that they possess high strength parallel to the crystal planes at 2,700° C, and that heat is rapidly and evenly distributed along the surface, makes their use in rocket engines and nose cones of considerable importance. The utilization of graphite in nuclear engineering and particularly in advanced gas-cooled reactors raises another singular feature of its behaviour, namely, its ability to reduce the internal stresses developed by irradiation through the mechanism of irradiation creep. The properties of graphite fibres, although they have only about half the mechanical strength of carbon fibres, are interesting, particularly at elevated temperatures.

In the discussion, attention was centred on the nature of the voids in graphites which apparently are normally small intercrystalline spaces (5–10μ). These, in addition to being able to be filled by impregnation, can also provide accommodation for creep. Delamination of graphite was found to occur because of the anisotropy of shrinkage resulting from the cone or circular type of growth exhibited in pyrolytic graphites. The high resistance to corrosion of graphitic materials was of value when used in the electrolysis of brine, and it was suggested that the particular orientation of graphite provided a system most capable of accommodating and resisting corrosion stresses.

The second paper, on "Steel Plant Refractories for High Temperature Processes", was given by Dr. J. N. Chesters (United Steels Co., Ltd., Rotherham). He began by summarizing the development of steel-making techniques from the original crucible process to the present-day electric arc furnaces. More than half the refractories produced in the world are consumed in steel-making furnaces. During the past decade there has been a radical change due in the main to the introduction of tonnage oxygen in the Bessemer-type of furnace. This has resulted in operating temperatures at least 100° C higher than normally used and concentrations of iron oxide many times those previously experienced. The use of high-current arc furnaces has also contributed to higher temperatures. Although material developments have arisen from work on atomic energy and rocketry, these have proved largely inapplicable to steel-making due to their instability under oxidizing conditions and their inadequate resistance to iron oxide. It seems that the development of suitable materials for furnace linings is very likely to come from the use of modified conventional materials; for example, in the use of denser materials of higher purity fired at unusually high temperatures. As a replacement for the conventional fire-clay and silica bricks, increased use has been made of basic refractories, particularly dolomite and magnesite. Many of these are used in the unfired state—frequently tar bonded—and it is increasingly certain that the carbon resulting from the tar plays a vital part in resisting slag attack.

Even the densest of these dolomite refractories are, however, proving inadequate for the worst conditions, and the latest swing is towards increasingly pure magnesia either in the fired or unfired state. Bricks made from relatively pure magnesia, fired at high temperatures, are also possessed of unusually high thermal shock resistance. A further decrease in porosity would be likely to improve this performance still more. Another major development has been the use of high alumina (85–98 per cent) bricks.

In the discussion which followed, Dr. Chesters instanced many cases of anomalous behaviour in refractory furnace linings, and pointed out that very little was really known about the atmosphere inside the furnace and the precise mechanism of attack. In one case, for example, a layer of special high-resistance material set in dolomite was found to have distorted considerably more than expected. The question of whether or not a better performance was obtained with fired or unfired materials probably depended on the relative conductivities and the penetration of the slag melt into the refractory. Graphite had been used as a furnace-lining material in the United States, but it was known that graphite burns rapidly in the presence of oxygen, and therefore some experiments had been done to reduce the oxygen concentration in the furnace atmosphere by replacement with nitrogen or steam. There was a suggestion that the considerable increase in temperature in certain areas of the lining leading to rapid breakdown was due to the influence of plasma jets which, of course, were capable of generating extremely high temperatures.

Mr. J. P. Proctor (Pilkington Brothers, Ormskirk) next gave a talk on "Glassy Materials". Three types of compound are found in normal glasses: (*a*) network-forming compounds which are oxides of such elements as silicon, phosphorus, boron and germanium; (*b*) network modifiers which are essentially alkali metals such as lithium, magnesium, caesium and barium; (*c*) intermediates such as the oxides of beryllium, aluminium, zinc and lead.

It was also possible to produce glasses containing fluorides, sulphides, tellurides, etc. In the laboratory at least, the properties of glass can be tailored to cover a wide range of specifications and the important factors in obtaining the desired result are: (1) chemical composition, and (2) the thermal history—important aspects of which are the transformation temperature, the strain release temperature and the annealing temperature.

Methods of improving the strength of glass include chemical toughening as exemplified by the replacement of small by large ions using diffusion processes. Strengths in the range 50,000–80,000 lb./in.^{2} can be obtained in this

way. All glass-like substances are prone to the process of devitrification but, by the use of controlled nucleation with elements like gold, silver or copper, the crystallinity can be controlled, and this technique, together with chemical toughening, can provide glasses with strengths in the range 100,000–250,000 lb./in.^{2}.

Mr. Proctor showed how the use of silver halides in a glass of the sodium–boron–silicate type gave a photochromic substance which darkened on exposure to light.

Questions on the properties of different glasses revealed that it was possible to produce complex structures made up of layers of different glasses.

Some discussion followed on the use of slag/ceram compounds as building materials, and Mr. Proctor pointed out that it is necessary to control the crystallization in order to preserve strength. For this reason it was impossible to roll β-eucryptite glass without destroying the crystallites since any subsequent treatment always tended to alter the crystalline nature. It was apparently not possible to modify the surface properties of glass in order to reduce the amount of condensation which occurred in Britain's humid climate!

Mr. R. W. Nichols (Reactor Materials Laboratory, Culcheth), in his talk on "Recent Developments and Future Prospects for Ferrous Materials", said that a growing understanding of the mechanisms available for strengthening metals, coupled with new production processes which permit greater freedom of composition, is enabling the development of structural steels with higher strengths than the mild steel which they are beginning to replace. One method of strengthening steel is the introduction of additives such as carbon or other alloying elements which act as obstacles to fracture propagation. The proportions of these additives must, however, be kept to a minimum in order to avoid affecting the toughness and welding characteristics of the steel. A striking example of alloying developments is the series of maraging steels giving weld strengths of 90 tons/in.^{2} upwards with excellent weldability.

The important requirement of steels for high-temperature usage has involved work to determine the parameters controlling high-temperature strength and high-temperature oxidation resistance. In addition to employing alloying techniques, considerable gains can be made by the more efficient use of existing materials, as a consequence of a better understanding of the limiting failure processes. Control of the grain size can, for example, be achieved by the use of aluminium (as AlN) and niobium (as NbC). Further improvements can be made by increasing the purity of steel—most important is the reduction of sulphur—and also by the use of hot rolling techniques to break up the carbides into smaller particles.

After this paper it was decided to proceed without discussion to the joint contribution by Dr. A. R. Harding (Aluminium Laboratories, Ltd., Banbury) and Mr. R. W. George (Royal Aircraft Establishment, Farnborough) entitled "Aluminium and its Alloys". This paper, incidentally, provided an encouraging example of a joint approach by supplier and user. Dr. Harding described the present stage of development of aluminium alloys, showing how their properties and application are already well exploited, and pointing out the importance of the economic factors in deciding what materials should be developed and how they should be produced. He then showed how the present development of conventional alloys is governed by the need to satisfy conflicting requirements. Mr. George then discussed the improvement of fatigue properties in aluminium and its alloys and showed how increases in tensile strength obtained in the development of aluminium alloys have not been accompanied by proportionate increases in fatigue strength. From various metallographic studies it became increasingly clear that the plastic deformation resulting from cyclical loading can break down or destroy those micro-structural features which confer tensile strength. In attempting to develop an improved aluminium alloy, a material containing 5 per cent magnesium was selected, since this alloy, although of low tensile strength, has a relatively high fatigue strength. Improvements in tensile strength were attempted by further alloying without interfering with the intrinsic fatigue-strengthening mechanism of the aluminium–magnesium matrix. Various aluminium–magnesium–copper and aluminium–magnesium–zinc compositions have been made and tested and an aluminium–zinc composition was chosen as a working basis for further development.

Discussion on improvements in ferrous metals showed that again developments centred on the principle of limiting fracture by the use of additives, and by careful attention to control of grain size. The use of carbon, for example, could be tolerated provided the carbides formed were small and uniformly distributed; weaknesses were often encountered due to the lath-like shape of certain carbides. It was also observed that inter-metallics can occur as small brittle particles in the matrix, and this leads to fracture. Pearlite colonies can also contribute to fracture as these show weakness across the lamellae.

There was a suggestion that in view of the endless series of papers describing work on aluminium containing 4 per cent copper, very little progress has been made in commercial aluminium alloys over the past 10 years or so. Dr. Harding said that this surely indicated that aluminium–copper alloys cannot be extended into the more sophisticated requirements range and he felt that we had reached the maximum degree of improvement which can be achieved by purely empirical methods. It was time for science to have a look-in. Improvements in materials can be obtained by the trick of keeping some of the additives in solution so that they would be available for precipitation when the appropriate conditions were encountered.

The first day's discussions ended with a dinner attended by about fifty delegates at the Shillingford Bridge Hotel. After the meal the meeting was addressed by Dr. P. Murray (assistant director of the Atomic Energy Research Establishment).

Dr. Murray summarized the advances made in reactor technology at Harwell since its formation. The increasingly severe operating conditions demanded by these advances had made necessary the creation of a whole range of new materials with highly specific properties. These developments had been shared by a number of the divisions at Harwell and had, in fact, represented a truly 'materials science' approach to the solution of problems.

A vigorous discussion followed Dr. Murray's talk in which the economics of development on such a scale was often mentioned even to the extent of one member suggesting that the country and the tax-payer would be better served by closing down Harwell altogether!

The theme of "Recent Advances in Particular Fields" was continued at the start of the second day by a lecture from Dr. K. Newman (Imperial College of Science and Technology) on "Concrete". He remarked that the most useful properties of concrete are its ability to be moulded easily into any shape in the fresh state, and its high compressive strength and durability in the hardened state. Its main disadvantages are its low tensile strength, which has led to the use of mild and high tensile steel as reinforcement, and the considerable shrinkage it undergoes on drying out. Despite its widespread use little was known until recently about the structure of concrete and how this affects its physical and mechanical properties. The internal structures of hardened cement pastes, mortars and concretes were briefly described and their influence on stiffness, strength and the mechanisms of shrinkage and creep were explained. It was then apparent that considerable advantages can be gained in the use of concrete as a structural material by providing even a moderate, reliable tensile strength and a significant reduction in shrinkage. Several methods of improving tensile

strength were proposed, including the use of aggregate of similar stiffness as hardened paste to reduce stress concentrations, the formation of chemical bonds at the aggregate–paste interface, and the introduction of small pieces of steel wire, glass or other fibres to arrest crack propagation. Most of the adverse effects of shrinkage can be overcome by more sensible construction techniques. However, drying shrinkage can be reduced considerably by sealing the concrete in impermeable surface finishes, by the use of expanding cements, or by steam curing at temperatures more than 180° C. A range of materials with properties between those of concretes and ceramics could be produced by autoclaving low water content, pressure compacted, concrete products.

In considering methods of reinforcing concrete, Dr. Newman during the discussion indicated that a large number of different additives had been put into concrete, including organic reinforcement; the only criterion to emerge from these trials was that for satisfactory performance the reinforcing material should be stiffer than the material into which it is placed. The presence of a large number of small cracks also served to increase the strength of concrete by acting as fracture terminators.

After this, Dr. H. Corte (Wiggins Teape, Research and Development, Beaconsfield) gave a talk on the development of paper and board. The early use of paper was confined almost entirely to writing and printing and it was only the application of mechanization, leading to increased production of cheap paper, which opened up new fields of application. These come into four main categories: (*a*) Packaging paper (such as disposable milk containers and multi-wall corrugated containers). (*b*) Sanitary papers (such as disposable incontinence pads). (*c*) Communication papers (such as '*NCR*' paper and electrographic copying paper). (*d*) Special technical papers (such as the eighteen different functional papers which are used in and for the motor-car).

In attempting to improve the performance of paper, three essential properties of the material must be borne in mind. These are: porosity, sensitivity to water, and strength.

Paper has a random porosity with a considerable variety of pore sizes. This scatter can be a disadvantage in such applications as oil filters, etc. Control of porosity can be done by various techniques including coating, which is often done for other reasons and also by the closure of pores as in the preparation of vegetable parchment by sulphuric acid or chloride ions. The mechanism of this latter technique is not yet fully understood but is being investigated. It is also possible to reduce porosity by means of resin impregnation. Multiple spark techniques can also be used to impose a controlled porosity, and, finally, the porosity can be further reduced or eliminated by lamination with plastics or aluminium foil. The sensitivity to water depends mainly on the presence of hydrogen bonds, and two techniques are available for increasing wet strength. Either additives which form bridges can be used, or alternatively, the incorporation of plasticizers (as in the wrappings of sweets) can be effective. Paper tears essentially by delamination, and improvements to tear strength are achievable by coating with latices or by impregnation with epoxy resins. A more advantageous fibre distribution (felting) can also be used but the technique is difficult.

Dr. J. P. Berry (Rubber and Plastics Research Association) next gave a talk on plastics. He began by indicating the close relationship between some of the materials called plastics impregnated papers by Dr. Corte, and visualized as paper reinforced plastics by himself! Plastics have many attractive properties but their complex mechanical behaviour poses problems in design. Inadequate understanding of these problems has tended to restrict the use of plastics to non-critical applications or has resulted in over-conservative and hence uneconomic design. In selecting a plastic for a particular use it is necessary to establish the factors which will render it unserviceable. After this the mechanical properties will determine the dimensions of the fabricated component. By achieving an understanding of the properties and limitations of plastics, and in particular the effect of time and temperature, more efficient use can be made of existing materials in present applications, and extensions can be made to new applications. There also will exist the possibility of developing materials with special improved properties.

In reply to a question on the use of paper fabrics, Dr. Corte pointed out that the principal difficulty was to achieve a satisfactory drape, and also indicated that the paper fabric-like non-woven materials were mostly composed of non-cellulose materials and were therefore expensive. Cheapness in 'paper making' depended on long runs, and the type of run used in textile production would be quite uneconomic. There was, however, a development in the United States of such disposable items made from paper as laboratory coats and hospital sheets.

Several members raised the question of ageing, odour absorption and unattractive appearance associated with plastic domestic utensils. Dr. Davies pointed out that articles which were cheap were often 'nasty' and both he and Dr. Berry emphasized that improvements were continually being made to plastics, and that it was also necessary to educate consumers in the choice of suitable materials. There was some discussion on the similarity of paper and wood, particularly in the case of some resin-reinforced products which Dr. Corte showed. The difference between wood and paper depended on whether or not the lignin was left in or removed from the product.

General trends of development in materials science. This session began by a survey of 'Fracture' by Mr. S. F. Pugh (Metallurgy Division, Harwell). Mr. Pugh plunged straight into classical materials science by observing that Galileo was wrong in assuming that the strength of materials was independent of dimensions, and remarked that Leonardo da Vinci found after experiments with iron wires of different lengths that tensile strength was dependent on the length of the specimens. It was suggested that a longer specimen contained more dislocations. A knowledge of fracture mechanisms may help both in the development of materials with improved fracture resistance and in improving engineering design techniques. Similarities and differences between the fracture characteristics of materials with as wide a variety of structures as mild steel and magnesium oxide were discussed. In developing a coherent science of fracture of materials, the subject can be divided in different ways according to the criterion adopted. So far there is no way of predicting which types of fracture a new material will suffer, because the critical factors are not known. Further investigations of fracture mechanisms are required, perhaps with more attention being paid to comparison of a given type of fracture in materials of widely different structure and physical properties. A complementary problem is in finding the relevance of the various fracture models to each particular type of fracture in each type of material. Mr. Pugh gave examples of the phenomenon of ductile fracture in glassy polymers subjected to prolonged stresses and said that a typical instance was to be found in stainless steel. He also dwelt on the use of reinforcing agents and, like Dr. Newman, indicated that it was often effective to set a crack to stop a crack, and instanced the poor bond between the reinforcing material and the resin in fibreglass as a means of providing a strong composite.

In the discussion it was observed that as materials were produced which had greater strength, the problem of brittleness became more acute and much of the work on improvement of materials lay in the reduction of brittleness. A technique was the provision of a multitude of crack-inhibiting centres. These can be either voids (as in the case of graphites) or particles and voids as produced in refractories resistant to thermal shocks by the incor-

poration of ground-up bricks in the clay matrix. Soft reinforcements in materials like concrete would also achieve the same end.

Dr. C. Edeleanu (Imperial Chemical Industries Materials Group, Billingham) then spoke on the development of engineering materials. The factors which have to be considered when making the critical decision of what material to use in an engineering application are: (1) What materials are available. (2) Costs—not of the material itself, but of the whole job, including processing and fabricating. (3) The time limit—whether or not the material can be developed and processed in the time available. (4) Human factors which include whether or not the material is pleasing in the particular application.

All these factors, but particularly the last, entail close co-operation between the designer, the fabricator and the user. It is also essential to understand the real and not the alleged requirement of a product, since often the customer does not really know what he wants. It was pointed out also that in many cases important developments occurred not in the material but in the development and use of economical ways of fabrication and production. Examples of this type of improvement emerged in the discussion particularly with reference to the manufacture of aluminium and the continuous process for steel fabrication.

Mr. J. M. Hutcheon (Reactor Materials Laboratory, Culcheth), in his talk entitled "A Plea for the Humdrum", said that although the development of new materials to the full scale in a very short time is possible, it is very expensive, and can only be undertaken under very exceptional circumstances. In most countries, for most of the time, the requirement is that the investment in research and development be kept to a reasonable proportion of the gross national product. There is, however, still ample scope for the materials technologist to use his influence with the engineer to ensure that materials specifications are rationally related to the proposed use; to investigate also the causes of variability within what is nominally the same material, and to seek means of improving existing materials by relatively small changes in the manufacturing route. This shifts the balance of research and development responsibilities away from the user laboratories into those of the manufacturer. Rapid test procedures are required, together with the detailed examination of every stage of the manufacturing process, and it is possible that some central organization such as the Ministry of Technology should finance developments.

The speaker also pleaded that university graduates should work in operating plants. He also pointed out that the statements made in his talk underlined the necessity for co-operation between user and manufacturer at the earliest possible stage of a project.

The final paper in this session was given by Mr. J. E. Gordon (Explosives Research and Development Establishment, Waltham Abbey). The speaker wondered whether the practice of cheapening a material in order to extend its market was making the most economic use of Britain's scarce research resources. Bessemer was said to have reduced the cost of steel by a factor of 5, but it is unlikely that the cost of mild steel could be reduced in the future by so much as 20 per cent. If this did happen, the value to the motor-car user, and perhaps the economy as a whole, would be no greater than a reduction of 1 per cent on petrol consumption. Reductions in the region of 25 per cent in petrol consumption could clearly be achieved by cutting the weight of the car. It is therefore arguable that steel is too cheap and if it were more expensive manufacturers would produce more efficient designs. Cheap materials may be as doubtful a blessing as cheap labour. Improved materials development could produce two benefits: (*a*) a more efficient product by weight saving, or (*b*) cheaper fabrication, since the cost of fabrication is nearly always much greater than that of the material.

The former point is receiving much attention, but the latter needs further consideration. Mr. Gordon believes that we may be nearing the end of the road with regard to cheapening existing metal-working processes, and we must begin to think more about moulding and casting processes. Some attention should also be paid to two-component systems, and here one can either increase the strength while leaving the density constant, or leave the strength unchanged and reduce the density. This could be achieved with steels, but not with some of the intrinsically lighter materials. An example would be the reinforcement of soft steel with hard ceramics; also, the quantity of wood consumed per year is about 10^9 tons compared with 4×10^8 tons of steel. Wood is cheap and has a similar modulus to steel, it has low density but does have other disadvantages. Could not more use be made of it? Plastics have too low a modulus to be used much as engineering materials, but might be modified. The use of very small quantities of reinforcement—less than 2 per cent—was found to give startling increases in mechanical properties. The discussion included remarks on the cost of training graduates, the type of training normally given to Ph.D. students and a suggestion that universities are far from being bands of learned men training intelligent machines. The only reason for research is to keep the teachers' minds alert in their task of machine training. It was also suggested that different fabricating techniques should be combined to provide new components based on design requirements and it was also contended that the policy of planned obsolescence, so prevalent in motor-cars, should be extended to things like houses so that the owner of a plot of land can replace his house easily and cheaply every 10 years or so.

Economics of new materials development. It was intended that most of this session should be devoted to a general discussion of topics raised in the Conference as a whole, and by way of a curtain raiser Mr. F. Roberts (Chemical Engineering Division, Harwell) gave a short talk on the economics of new materials development. He emphasized the importance of correctly allocating costs in any manufacturing operation and suggested that the important factors were: (1) raw materials, (2) power consumption, (3) capital costs, (4) reject rate and recycling costs, (5) degree of quality control (inspection), (6) scale of production (that is, (*a*) bench scale; (*b*) experimental or pilot scale; (*c*) large scale), (7) research and development charges.

In considering raw material costs it is necessary to consider the economic advantages of either starting with pure materials and ensuring they are kept clean during processing, or by starting with cheaper and less pure materials, and incorporating a refinement stage during the process. Turning to the question of continuous or batch production, Mr. Roberts emphasized that if continuous production were used it must be really continuous, since stoppages would inevitably affect the whole production system.

Finally, he emphasized the advantages of costing as early as possible in the development of the process.

Dr. Chesters began the discussion by pointing out that although labour costs were often the target for economy they were in many cases a small fraction of the total bill. For example, in the production of a ton of steel the total cost was £25, of which the main single item was £14 for scrap and only 7*s*. for labour costs. It is, therefore, better to improve techniques or to improve the quality and lasting power of such things as electrodes than to attempt to economize on labour costs. It was suggested that the number of different types of steels could profitably be reduced, but against this there was the position that the customer insisted on a variety to meet his own needs, and if this were not supplied would simply go to someone who was prepared to make it for him. There was agreement, however, that often the customer did not know what he wanted, and that there was a need for a closer

investigation of requirements. Also, such matters as methods of test could easily be undertaken by joint user co-operation. If this co-operation were further extended and the users could be persuaded to do more research on requirements, it would then be possible to bully suppliers more successfully, and oblige them to provide new materials with properties which were really needed.

Some discussion ensued on the differences between the development of a new material and a new product. In the former case the development was usually for a specific purpose, whereas in the latter, having made the development, it was often necessary to search for a market. There were dangers attending on the change of manufacturing processes from, say, batch to continuous operation, since the product often possessed different properties, and it had been found in the past necessary in some cases to start from different raw materials.

Some surprise was expressed at the lack of satisfactory composite materials, and this was attributed to the fact that scientific method had only recently been devoted to the development of composite materials. These were very often very expensive in the early stages and also the techniques were often time consuming. However, it was felt that considerable advances in composite materials would occur over the next few years.

It is impossible to sum up in a few words a conference which covered such a wide field of materials and ideas, but a point which emerged very strongly—and which was commented on by a number of speakers—was the very keen interest displayed by lecturers and contributors to the discussion alike in economic matters. Even during a discussion on what the organizers felt would be purely technical matters, the conference was continually being reminded of the need to consider economics.

W. A. Holmes-Walker

IDENTIFICATION OF ELUTED COMPONENTS IN GAS CHROMATOGRAPHY

An informal symposium with "Identification of Eluted Components" as the main theme was held by the Gas Chromatography Discussion Group of the Institute of Petroleum on September 23, 1965, at the Bodington Hall residence of the University of Leeds. The members were officially welcomed to the University by Prof. H. M. N. H. Irving.

The first paper, presented by Dr. R. P. W. Scott (Unilever Research Laboratories, Colworth House), summarized recent work on the development of a chromatograph that would operate intermittently, allowing a 15-min time interval to elapse after the elution of each peak.

Experience in the separation of complex mixtures had shown that simultaneous low-resolution mass and infra-red spectra were needed to assign identities unequivocally to peaks. This being so, a single chromatographic run extending to as long as 24 h with each eluted component being given the attention it deserved could result ultimately in a net gain in analysis time, particularly if compared with duplicate runs, one for high-speed low-resolution mass spectrometry and the other for trapping and regeneration of samples for infra-red examination. Tailoring the gas chromatographic and infra-red equipment to meet the preferred approach was the subject of the presentation.

Because of the time needed to make a normal infra-red scan, it was essential to be able to stop the chromatographic run for a 15-min period without adversely affecting the chromatographic resolution of components still in the column. This was found to be possible using a set sequence of stopping the carrier gas flow at the exit of the column, directly after trapping out a peak and releasing the column pressure at the inlet. Elution was re-started when required by opening the inlet and outlet valves and re-applying the column pressure evenly over a period of about 30 sec. This procedure has found extended applicability for the analysis of flavours using a 60-ft. packed column having a performance of 30,000 theoretical plates.

To obtain the desired mass of component in the infra-red cell a concentration step was required; this has been achieved by condensing each fraction on to a 10-cm column packed with 40 per cent 'Carbowax 200 *M*' at ambient temperature, from which it is automatically eluted rapidly at high temperature into the infra-red cell. A sixty-fold concentration is possible by this means. Simultaneously with the infra-red examination, a mass spectrum would also be obtained using a low-resolution mass spectrometer, such as '*M.S.* 10', which would give similar resolution to the normal fast-scan mass spectrometers but at less than one-fifth of the cost. For infra-red spectra, a normal '*SP.*200' infra-red spectrophotometer with a 15-min scan has been used for which 25 μg of sample was adequate, provided the cell was designed so that the sample was situated wholly in the light path. A suitable heated cell, plated internally to minimize adsorption of sample and with a total volume of 25 ml., was described and the determination of the spectrum of eugenol which has a vapour pressure of 30 mm at the cell temperature of 150° C was cited as an example of its use.

The whole sequence of events has been automated to such an extent that injection of the sample in the first instance is the only manual operation required.

The next paper, presented by Mr. L. Davies ('Shell' Research, Ltd., Woodstock Agricultural Research Centre, Sittingbourne), dealt with the problems of identification encountered in the determination of pesticide residues in crops, soils, etc., where the solvent extract can often contain very much less than 1 p.p.m. of pesticide together with large amounts of co-extracted material.

The electron capture ionization detector, which possessed selective response to certain halogenated compounds at levels below 10^{-9} g, had been used successfully with both planar and radial arrangements of anode to cathode using a d.c. mode of operation with oxygen-free nitrogen as carrier; undesirable ionization effects had been observed when using argon. The halogen sensitive leak detector in its several forms (Associated Electrical Industries, Ltd.) was also useful as a gas chromatographic detector at the nanogram level although to achieve this sensitivity with acceptable base-line stability the electrode potential required optimizing and the cell (types *HA* and *J* had been used) should be operated in a stream of nitrogen. The electron capture and leak detectors were used to complement each other, in so far as when tied in series they exhibited differing relative responses to certain halogenated compounds. This enabled some degree of certainty to be attached to identification and considerably reduced the possibility of mistaking a product of low electron affinity present in gross amounts for a trace of chlorinated compounds, as was possible when electron capture was used alone. Chromatograms illustrating this type of application were shown. While the linearity of response of the leak detector cell was about three times that of electron capture and the elements are inexpensive, a degree of electrical instability and the need for conditioning are features that have to be contended with. Mr. Davies pointed out, however, that the cells were being used for an application for which they were not designed.

For non-halogenated organo-phosphorus pesticides a sodium thermionic detector, adapted from a flame ionization detector by fusing sodium sulphate to a platinum wire collector electrode, had been the subject of investiga-

tion. A response to nanogram quantities of organophosphate pesticide had been obtained by increasing the electrode temperature but this had resulted in rapid loss of selectivity and base-line stability; similar characteristics were found when other alkali metal salts were used and when the salt was introduced into the flame at various positions. Some reduction in the rapid loss of selectivity at high-sensitivity settings had been obtained by using a tube of thin platinum 1 mm in diameter filled with sodium sulphate as the 'pick-up' electrode. There was considerable scope for development of this detector and the leak detector for use as selective detectors in gas chromatography.

Using the chromatograms obtained for a mixture of *n*-alkane, iso-alkane and alicyclic hydrocarbons, Dr. D. R. Deans (Imperial Chemical Industries, Ltd., Heavy Organic Chemicals Division, Billingham), in the third paper presented, showed that superior separation of certain components difficult to separate could be obtained by using two columns of different type in series and backflushing part of the sample through the first column at some critical stage during the elution. The degree of separation which could be achieved was better than could be obtained by straightforward elution through either of the columns used alone or in series. In addition to this novel application of backflushing there was also its more conventional use in conjunction with pre-columns for isolating heavy components. Despite these applications, the technique was not widely used and Dr. Deans thought this was due to the mechanical difficulties of operating taps enclosed in ovens and the attendent contamination of sample with grease and increase in dead volume causing band spreading. These objections had been overcome by using a system in which a capillary *T*-junction was used to connect the two series columns with one limb of the junction extending outside the oven to the control system. Similarly the controls for injection and backflush vent were outside the oven (for details see *J. Chromatog.*, 18, 477; 1965).

The combinations of columns (two packed, two capillary or packed and capillary in series), of liquid-phase type on the columns, of cutting and of treating the backflush (to vent or back to the column system) were innumerable. Fractions or compounds monitored out of the stream at some intermediate stage could be subjected to in-line reaction using micro-reactors or pyrolysis units. A fascinating example of this type of application was described in which the identification of the components of a complex mixture of heptenes, for which pure compounds for use as references were not available, was achieved by hydrogenating monitored peaks and re-chromatographing them against the more readily available saturated hydrocarbon reference compounds. Operation of the various systems described was considered to be very simple in practice and a switching unit had been constructed for connexion to any existing chromatograph allowing all possible schemes of operation to be used.

Mr. M. B. Evans (Natural Rubber Producers' Research Association) described his work concerned with the role of the solid support in retention measurement. One aspect which had been investigated was the apparent increase in polarity of non-polar liquid phases when used under conditions where oxygen is not rigorously excluded from the column. The retention characteristics of a wide range of solute types on freshly prepared squalane columns to which known weights of high molecular weight alcohols, aldehydes and ketones had been added were compared with retentions on a squalane column which had been deliberately oxidized at 100° C; for the columns with added oxygenated compounds there was evidence to show that retention indices are linearly dependent on oxygen content, whereas for oxidized columns there was an initial drop in retention for polar solutes (also a pronounced reduction in peak tailing) followed by an increase. It was suggested that the initial drop observed was due to the first formed strongly polar compounds deactivating the surface and the values at the minimum of the curve corresponded to the retention index due to true partitioning in the squalane.

Evaluation of a number of glycols as support deactivators led to the conclusion that diglycerol was most efficient and its use had enabled improvements in peak symmetry and reduced solute isomerization and decomposition. Detailed investigation of the effect of diglycerol-treated support on the retention of weakly polar solutes by dinonyl phthalate and squalane phases showed retention to be almost independent of the ratio of liquid phase to the diglycerol deactivator; the retention of polar solutes such as alcohols was found to display marked dependence similar to that observed when squalane was oxidized.

It was considered feasible that the extent of the initial high retention of polar solutes when low liquid phase loadings were used could be a measure of the support activity. The evaluation of a wide range of support material using squalane as the liquid phase and a wide range of solutes at constant sample size provided convincing evidence that support activity could be measured in this manner and indicated that a commercially available silane-treated product was the least adsorptive of those investigated. It was also considered that an evaluation of the support could be made by the reversed procedure of assessing the extent of the deactivation of polar groups of the liquid phase by the support at constant proportion of liquid phase, thus the highest retention index for a polar solute should be given by the least active support. This was confirmed experimentally using polyethylene glycol liquid phase on the same range of supports as were used for the other investigation.

The final paper of the symposium was presented by Dr. J. F. K. Huber (University of Amsterdam) under the title "Two-Dimensional Gas Chromatography". He discussed factors relevant to the identification of components using two columns having different liquid phases as coatings. After listing the various forms of retention by which a solute could be characterized, Dr. Huber examined in some detail the factors affecting the accuracy of such data, among which were effects due to interfaces, pressure, flow changes and non-linearity of the partition isotherm. The results obtained by sample injection into two different types of column could be correlated by combining relative peak area values and known retention values although one source of error was the presence of masked peaks. With two columns combined so that fractions of the effluent from the first column were injected into the second column more definite results could be obtained as well as enrichment of a trace relative to a main component.

C. G. Scott

URBAN TRAFFIC PROBLEMS

A MEMORANDUM issued by the Ministry of Transport/Scottish Development Department deals with the principles of applying traffic engineering techniques to urban road traffic problems*. It is designed to enable suitable short- to medium-term solutions to be found for urgent traffic problems, while providing a useful guide to the wide range of traffic engineering methods and techniques, many of which must be used in formulating the long-term traffic solutions which will be incorporated in comprehensive land use/transport plans. It does not attempt to give guidance on the surveys needed for

* Ministry of Transport/Scottish Development Department. *Advisory Memorandum on Urban Traffic Engineering Techniques.* Pp. xi + 92. (London: H.M.S.O., 1965.) 7*s.* 6*d.* net.

preparing these plans. The shorter-term traffic solutions should not be looked at in or by themselves, however, but should be viewed so far as possible in relation to parking policies, to the needs of environmental as well as traffic management and to the likely ultimate pattern of town roads. Together they constitute the broad approach to the problem of traffic in towns; in particular, any short-term proposals which would determine road widths or alignments for a long time ahead should be carefully considered in this wider context.

The memorandum includes a report on a preliminary reconnaissance to identify the nature of traffic problems, the information available on traffic data, accidents and land-uses, and the extent to which further information is needed. This is followed by a section on methods of taking traffic censuses, origin and destination surveys, surveys of public transport, measurements of speed, parking surveys and of collecting accident data. In the third section, the processing and presentation of survey information ready for some formulating scheme are considered, and in the fourth, the design of short-, medium- or long-term schemes to meet the needs of both traffic and road safety. The fifth section considers methods for comparing the advantages and disadvantages of alternative proposals, including the economic assessment of road improvements, and, in the sixth section, investigations needed to verify the adequacy of the measures taken and to reveal any need for further measures are discussed. Finally, the value of quantitative assessment of traffic problems and improvement schemes, the need to study and train engineers in the methods of meeting traffic requirements and to take advantage of new, or little-used, techniques are considered.

New methods of meeting traffic problems, such as new types of signal-controlled pedestrian crossings, "give way to traffic from the right" signs at roundabouts, the use of vehicle presence detectors, tidal traffic working and area traffic control, are likely to come increasingly into use as their possibilities are explored, with also increasing application of pedestrian segregation, channelization, urban motorways, and grade-separated systems. Short-term measures may offer much relief of congestion at little cost, and waiting restrictions, banning of right turns, or one-way systems often increase road capacity by 20 per cent or more. Improvements of 20 to 50 per cent can often be effected at signal-controlled junctions, by rephasing and simplifying the traffic pattern, by restricting certain movements, or by small carriageway widenings at the signal approaches, as well as through increasing use of the more flexible modern traffic signal controllers to meet peak-hour demands.

With medium-term measures, the emphasis should be on junction improvements, provision of roundabouts, new signal-controlled junctions and widening roads, particularly at junctions or bottlenecks. In narrow streets lay-bys for buses or delivery vehicles can be of great value in promoting a freer flow. Traffic engineering techniques can help longer-term measures which require programming in order of priority. In determining priorities and in designing various schemes for new or improved roads and junctions and general road layout, to meet the future requirements of a town, it is emphasized that in establishing environmental areas and freeing them of unnecessary traffic, the traffic on the primary road network will be increased, and the network must therefore be designed to take heavier flows.

SOCIAL INFLUENCES ON MEASURED INTELLIGENCE

THE November issue of *Educational Research* (8, No. 1) contains five separate papers on various aspects of the influence of social factors on the measured intelligence quotient (I.Q.). Taken together, they are of outstanding public interest. One paper is entitled "Further Evidence on the Effect of Date of Birth on Subsequent School Performance", by R. Freyman, and is based on a study of: (*a*) 3,419 children born during 1952–55 from eight streamed junior schools in different parts of Middlesbrough; (*b*) 4,120 children born during 1953–55 from seven streamed secondary modern schools, four grammar schools and two other selective secondary schools; (*c*) 364 junior school children attending remedial reading groups; (*d*) 312 children referred to the child guidance service; and (*e*) 156 children attending the day special school for educationally subnormal (E.S.N.) children. Among the children in streamed junior schools, of those born during the period September to December, 39·7 per cent were in *A* classes, 25·8 per cent in *B*, and 22·4 per cent in *C*, while of those born in the period May to August, 28·2 per cent were in *A*, 36·6 per cent in *B*, and 43·7 per cent in *C* classes. These differences were statistically highly significant, along with the finding that the percentage in the *A* stream increased with length of schooling.

Similar results were obtained from all the children attending secondary schools. Of those born during September to December, 36 per cent were in selective schools and 28·4 per cent in secondary modern schools, whereas, of the ones born during May to August, 32·3 per cent were in selective schools and 36·1 in secondary modern schools. Again, a larger proportion of younger than of older children obtained low and average marks.

Of the children in remedial reading groups, 46·7 were born during May to August, and 27·8 per cent during January and April periods, a discrepancy which was wider still among those referred to the educational psychologist because of backwardness in reading. The children attending the local E.S.N. school produced less clearly cut differences.

From his survey, Freyman concludes that the date of birth exerts a significant influence on a child's school grading, and that at junior level, streaming in schools tends to perpetuate differences due to date of birth. The disadvantages of the children born during May to August were greatest in those referred because of difficulties in reading; and "secondary psychological symptoms such as lack of confidence and emotional maladjustment were often displayed".

It might be thought that these discrepancies arise because children born in September to December are almost 8 years old when transferred from infant to junior schools as compared with the 7 or 7 and 4 months age of those born in the summer. But in itself, that factor, although real, can be allowed for; it does not account for the whole of the difference, which seems to be determined by some specific condition, not simply delayed mental development; and Freyman calls for a new educational deal for children born during the summer, which might include longer time in the infant school and more flexible forms of educational organization.

In his paper on "Date of Birth and Scholastic Performance", D. A. Pidgeon is concerned with the same kind of theme while carrying the discussion somewhat further. He makes the point that children who have had more schooling will have learned more and in examinations are likely to give better results; but in addition, children born in summer usually remain the youngest in their group throughout the junior school, a situation which imposes additional stress. Supporting evidence comes from Sweden.

It is a moot point whether, as a whole, the innate intelligence varies as between children born at different

times in the year. This question can be approached only through tests, which at school age give results similar to those already indicated. To some extent it may be clarified through appropriate tests carried out on children of pre-school age. But at present, many children are handicapped for life through being born during summer months and having to fit into the teaching year.

Pidgeon thinks that the abolition of streaming would remove one obvious and distasteful effect, but "while classes consist of younger and older children, the younger may continue to suffer in other ways". To him, the only true solution would be the individualizing of learning, along with a change of approach from present class teaching methods.

In the next two papers, interest shifts to educational performance between different kinds of children and in different types of secondary schools. W. H. King writes on "Differences in Mathematical Achievement Related to Types of Secondary Schools and their Geographical Locations". This is part of a much larger study based on comparisons between children attending schools in South-East England and others in the twin cities St. Paul–Minneapolis, Minnesota. A special sampling technique was used on 58 secondary schools representing all the different English types, and in each the unit of testing was a complete form.

In addition to questionnaires completed by teachers and students, three standardized tests were used: Mathematics Test 1 by MacFarlane Smith; Co-operative Sequential Tests—Mathematics *STEP* Test; and Raven's Progressive Matrices, 1956 edition. 3,134 children had scores on all three tests. Taking grammar, technical, secondary modern, and comprehensive schools in order, on Raven's test the mean scores were 49·81, 49·72, 44·18 and 45·76; on the *STEP* test, 37·13, 33·44, 24·22 and 26·62; and on the Maths 1 test, 83·83, 80·28, 55·69 and 57·96. Contrasting pairs of schools were also tested. On Raven's test the differences were not great but they were very marked with the other two, particularly the Maths 1 test.

In all these tests, the grammar school scores were the least variable, the differences widening progressively in secondary modern, technical, and comprehensive schools, and especially because of wide differences in mean scores, with considerable overlap between schools. It is clear that comparisons between mean scores in different types of secondary schools are of little value. Nevertheless, it was estimated that two-thirds of the high ability group came from grammar schools, while three-quarters of children of low ability were to be found in secondary modern schools. Still, "no one type of school has a monopoly of students in the high or low ability category".

In his conclusions, King directs attention to the very wide gap in scores between children in grammar and technical schools on one hand and secondary modern ones on the other, suggesting that the causes, motivations and levels of aspiration are not linked solely with differences of ability. These points urgently need attention; and the research has uncovered a problem of raising the achievements of the lower ability group in secondary modern and comprehensive schools without lowering it in grammar and technical schools. Particularly in the two mathematical tests, the findings were disappointing. Clearly, in relation to mathematics, the minds of many children are not being fully stretched. That conclusion may also apply to the United States public schools with which the project is linked, where the students' scores again are relatively low.

King does not go on to discuss the social influences which might account for these differences. Instead, in a paper on "Meritocratic and Social Class Selection at Age Eleven", D. F. Swift approaches intelligence tests on school children from another angle. Drawing on the work of Floud, Banks and Halsey, he states that "in developing industrial societies, the educational system is replacing all others as an avenue of social mobility". His own research was carried out in the North of England, covering 132 families, and was designed to compare the attitudinal environment of the home with the ability of the children, making use of the 11+ allocation procedure. The group under test represented a 10 per cent sample of all families in two Local Education Authority Divisions. Taking parental occupational groups, under the State School Sampling Frame, I to VI, the 278 children who passed at age eleven plus were distributed in the order 108, 78, 62, 13, 13 and 4, while by contrast, of the 922 children who failed, the corresponding figures were 98, 120, 290, 44, 157 and 213. Grouped by social class, 60 per cent of the middle class children passed, and 40 per cent failed, as against 11 per cent of working class who passed while 89 per cent failed. Again, middle class children had a mean score of 117 in verbal reasoning, 122 in English, and 117 in arithmetic, as against working class children, whose scores in these respective subjects were 100, 103 and 101.

On these results, ostensibly, the British ideal of equality of opportunity is being met, but present psychological knowledge recognizes the importance of motivation in test performance. Had borderline cases been taken into consideration, one-half of the working class children but only one-tenth of those of middle class would have been rejected for grammar schools.

Swift then goes on to consider what should be the basis for the 'meritocratic' system of selection. It seems to him that because of similarities between value-orientations of middle class and school life, "the use of middle class children as a base group is justified"; but any scheme for the organization of talent-producing institutions would need to be based on research covering large numbers in many different areas. And it is important to bear in mind that perspectives must be concerned with the contribution of education to allocations in society, for which the first step would be to establish how far education was important in the total process of meritocratic or social class selection.

The longest and most far-reaching paper is by O. Ferron, on "The Test Performance of 'Coloured' Children". He is working at Najala University College, Sierra Leone. He draws on the findings of many surveys of which the following may be taken as representative. Many early I.Q. tests in the United States tended to show that white children were superior to Negro and Red Indian ones and that children of North European stock were superior to those coming from South Europe. In 1926, Hirsch measured the I.Q. of immigrant children, and found that the mean score of British Canadians was 93·8, French 85·3, Negroes 84·6 and Portuguese 82·7. But in the same year, Helmer devised tests which contained subject-matter relating closely to the life of Red Indians, in accordance with which when compared with them white children were definitely inferior. On the other hand, Rohrer attributed the low scores of Red Indians in other tests to such factors as differences in social and economic status, differences in cultural environment, language differences, differences in test motivation, and inaccuracies in estimating chronological age.

Another worker in the field was Pyle, who found that Chinese children attending public schools were superior to American ones in rote learning, but inferior in tests involving logical relationships and in speed of learning generally. Then, in 1930, the University of Hawaii published the results of testing 4,500 children in the United States and Hawaii—where differences in social status between Chinese, Japanese, Portuguese, Puerto Ricans and Filipinos have been much reduced—which indicated that when differences in environmental opportunities are not too great, differences in intelligence performance could be expected to be correspondingly small.

Early work on African children produced results showing that they were markedly inferior to the Whites. For example, Fick, in 1939, concluded that Zulu children

aged 10–14 were from four to five years behind children of European descent on American Army Beta tests, and Oliver, on work initiated in 1932, concluded that in East Africa only 14 per cent of Africans reached or exceeded the European mean. But results like these stimulated interest in environmental factors, such as illiteracy among parents, and extremely low standards among teachers in primary schools, together with the very poor equipment of native African homes.

Ferron goes on to point out that in Africa the gap between white and non-white children can be reduced by the use of non-language tests, but the cultural ways of life and patterns of child rearing are significantly different, as also are cultural modes and traditional attitudes; but he thinks that "it would be far more constructive to continue with the use of Western type tests, since African aspirations are in the direction of a western technological civilization". Indeed, comparisons between British and African test performance can be justified in that they show where emphasis should be placed in the matter of environmental deficiencies. As a result of an investigation which he began in Freetown in 1960 and completed in Zaria in 1964, he concluded that the test quotient of an African group is to a large extent dependent on the degree of assimilation of western culture. He emphasizes that for African children, "the difficulty of passing from one world to another as the child grows older, of living in two worlds simultaneously, and of acquiring the newly imposed and rather unrealistic symbols of success and status, represents a struggle for survival with which the biological struggle of the survival of the fittest can bear no comparison, for even those who survive the former appear to be emotionally, psychologically and intellectually maimed for life". But he does not despair of the future, although until a simultaneous attack is made on many fronts, progress will continue to be slow; and the effort should be spread over the whole educational field, from birth onwards. In this campaign, the chief impediments at the present time appear to him to be found. (*a*) in the school, because of a mechanical approach to teaching in the early years particularly, in the teacher's relative lack of facility in the use of the English language, through discouraging the child from asking questions and exploring his environment, severe and capricious corporal punishment, along with mental rigidity, and an attitude of dogmatic authoritarianism; (*b*) in the home, because of birth injuries and incidence of subsequent malnutrition and disease, certain early child-rearing practices that are in the nature of traumatic experiences, the nature of the emotional relationships between adults and children, illiteracy, mainly of the mother, and lack of appropriate stimulation in the home and neighbourhood environment, and lack of definite teaching on the part of older children and adults; and (*c*) in government action through lack of proper physical surroundings in home and school, and relative lack of stimulation from mass media of instruction.

Because colour prejudice and discrimination against coloured people are not so severe in Britain as in the United States, Ferron thinks that a useful link and exchange of ideas might be established between research workers in Britain and in other parts of the world.

EMISSION BAND SYSTEMS OF Ag_2 PRODUCED IN DISCHARGE

By Prof Choong Shin-Piaw, Wang Loong-Seng and Lim Yoke-Seng

Department of Physics, Nanyang University, Singapore

In recent years, use has been made of King's furnace by several workers in their studies of the band spectra of silver and other high boiling-point metals. As a result, five band systems of the diatomic silver molecule have now been found. They are: (1) the system λλ4100–5200 first studied by Ruamps[1] in emission, and later by Kleman and Lindkvist[2], both in emission and in absorption; (2) the system λλ2750–2850, by Ruamps[3] and by Joshi[4] in absorption; (3) the system λλ2640–2700, by Ruamps and by Maheshwari[5] in absorption; (4) the system λλ2560–2620, by Ruamps in absorption; (5) the system λλ2460–2560, by Ruamps and by Maheshwari also in absorption. According to the vibrational analyses of these workers, these five band systems have a common lower electronic state of vibrational frequency 192·4 cm^{-1}. It is generally believed that this lower state is the ground-state of Ag_2. More recently, two of us[6], making use of quartz absorption tubes in their investigations of the atomic and molecular spectra of silver, were able to detect the visible band system at as low a temperature as 1,100° C.

Following our work on the absorption spectra of silver, attempts have been made to obtain emission band systems of the metal in discharge. This discharge tube was made of fused quartz. It was composed of a central stem of length about 20 cm and bore of 8 mm, two shorter and larger end stems with flat windows, and two side-tubes enclosing cylindrical aluminium electrodes of rather great heat capacity. After having introduced a few decigrams of spectrally pure fine grains of silver through a detachable window of the stem and having distributed them evenly along the central stem, the discharge tube was set along the collimator axis of a Hilger medium-size quartz spectrograph. The central stem was then wound about with a nichrome heating coil, and wrapped in turn with asbestos cloth, so that its temperature could be raised electrically for vaporizing the silver therein. A platinum–platinum rhodium thermocouple, previously attached to the side of the central stem, served to indicate the temperature during heating. In performing an experiment, the discharge tube was connected to a pumping and feeding device for introducing pure neon at a pressure of about 1 mm of mercury which served for carrying an electric discharge. Preliminary tests showed that: (1) the temperature of the central stem should be raised to 1,100° C and preferably to 1,200° C to get sufficient amounts of silver vapour for the discharge; (2) the side tubes, in which electrodes were enclosed, should be surrounded by solid carbon dioxide in order to get rid of the troublesome OH bands in the emission spectrum; (3) the average life of the heating coil was about 6 h at 1,110° C, but it rarely exceeded 2 h at 1,200° C. A high-tension transformer furnishing a power of 150 W was used to run the discharge tube. Exposures ranging from 5 to 20 min were found sufficient to record the band spectra on Ilford '*HP*3 Hypersensitive Panchromatic' plates. Iron arc served as the comparison spectrum.

Under our experimental conditions, six emission band systems attributable to the diatomic molecules of silver have been found. Five out of the six systems are previously known in absorption, and one of them also in thermal emission. The new system is situated in the region λλ3150–3630. Vibrational analysis of the old and new systems reveals some interesting and important facts.

Visible system λλ4100–4700. About thirty bands have been observed in the region λλ4100–4700, and they are all degraded to the red. Most of the bands are found to group into well-marked sequences. With the dispersion used, which was about 50 Å per millimetre in this

region, no rotational structure of the bands was observable. All the bands, except those belonging to the last three sequences on the long wave-length side of the region, can be represented fairly well ($\pm$ 4 cm^{-1}) by the formula:

$$\nu = 23{,}005 + \left[152\left(v' + \frac{1}{2}\right) - 0{\cdot}3\left(v' + \frac{1}{2}\right)^2\right] - \left[193\left(v'' + \frac{1}{2}\right) - 0{\cdot}6\left(v'' + \frac{1}{2}\right)^2\right]$$

In this formula, ν represents the wave-number per centimetre of the band-heads, v' and v'' the vibrational quanta in the upper and lower electronic states of the molecule. It results from the foregoing formula that the fundamental frequencies of vibration at the upper and lower states are $\omega'_e = 152$ and $\omega''_e = 193$ cm^{-1}, respectively, and the origin of the system is $\nu_e = 23{,}005$ cm^{-1} ($\nu_{00} = 22{,}984$ cm^{-1}). Within the experimental error, these molecular constants are in good agreement with those found by Kleman and Lindkvist for the system λλ4100–5200. Hence the system produced in absorption and in thermal emission and our system produced by discharge are one and the same system. According to these workers, the lower electronic state of the system was the ground-state of Ag_2, and so they designated this system as system $(A - X)$. We shall see that whether the lower state of this system is the ground-state is still open to question.

In our emission system, the v'' progression corresponding to $v' = 0$ comprises eight bands. Now, in following this progression it is found that the vibrational quanta $\Delta G''$ decrease at first very slowly, but drastic changes occur at $\Delta G''_{9/2}$, $\Delta G''_{11/2}$ and $\Delta G''_{13/2}$. Indeed, the values of the first and fourth vibrational quanta are $\Delta G''_{1/2} = 191{\cdot}8$ and $\Delta G''_{7/2} = 190$ cm^{-1}, while those of $\Delta G''_{9/2}$, $\Delta G''_{11/2}$ and $\Delta G''_{13/2}$, as inferred from our observed data, are about 236, 239 and 217 cm^{-1} respectively; in other words, there are deviations of whole bands from the regular course of a band progression. Moreover, band-heads, well visible in the other sequences of the system, become vague in the sequence $\Delta v = -4$ and practically disappear in $\Delta v = -5$, $\Delta v = -6$ and $\Delta v = -7$. Beyond $\Delta v = -7$, a continuum sets in, which continues to as far as 4800 Å. No doubt, we have here an example of vibrational perturbation and predissociation. A similar example was observed by Choong[7] in the case of a band system of the molecule of TeO.

Although the banded region of the system stops in the vicinity of 4700 Å, we have found eleven weak and complicated bands in a region succeeding the continuum mentioned in the foregoing paragraph. The wave-lengths of these bands are:

4807·0, 4811·4, 4861·4, 4884·4, 4915·1, 4917·1, 4957·6, 4972·2, 4994·4, 5016·3, 5024·4 Å.

These bands cannot fit into the foregoing formula. They may be due to polyatomic molecule of silver or impurities.

Ultra-violet system λλ3150–3630. The remarkable feature of this new system is that it consists of two strong wing-like bands, and patches of weak continua and flutings which link with the wing tips of the bands. The wings are found to originate from the lines of wave-lengths 3280·7 and 3382·9 Å, that is, the first doublet lines of the principal series of silver, and are almost symmetrical with respect to the corresponding lines. Under the specified conditions of experimentation, the span of the λ3280·7 band and that of the λ3382·9 band are about 140 Å and 80 Å respectively.

The production of a continuous spectrum that joins on to the long- or the short-wave-length side of an emission line has been known for a number of cases, and the phenomenon was first investigated in detail by Oldenberg[8] in the fluorescence spectrum of mercury vapour to which inert gases at high pressure had been added. In our case, it seems fairly certain that the wings are arising from a transition between an unstable upper state and an unstable lower state of Ag_2 resulting from $Ag(^2P_{1/2,3/2}) + Ag(^2S_{1/2})$. In regard to the patches of weak continua and flutings, they might be due to weakly bound molecules of Ag_2 or AgNe.

It may be of interest to point out that the doublet lines in question, produced in absorption[6] under neon at a pressure of 30 cm of mercury and at a temperature of about 1,200° C, were found to have a broadness of the order of 3 Å only. On the other hand, the same doublet lines, produced by a silver arc in an atmosphere of air, were found to be strong and to take the form of wing-like bands similar to the bands obtained in discharge. In the light of the present investigation, it may be said that unstable Ag_2 resulting from $Ag(^2P_{1/2,3/2}) + Ag(^2S_{1/2})$ must exist in prominent abundance in a silver arc.

Ultra-violet system λλ2750–2880. Twenty-one bands have been observed in the region λλ2750–2880. They are all degraded to the red and their heads can be represented in good approximation ($\pm$ 4 cm^{-1}) by the formula:

$$\nu = 35{,}646 + \left[180\left(v' + \frac{1}{2}\right) - 3{\cdot}8\left(v' + \frac{1}{2}\right)^2\right] - \left[207\left(v'' + \frac{1}{2}\right) - 0{\cdot}1\left(v'' + \frac{1}{2}\right)^2\right]$$

From this formula it may be seen that the values of ω'_e and ω''_e are 180 and 207 cm^{-1} respectively, and the value of ν_e is 35,646 cm^{-1} ($\nu_{00} = 35{,}631$). It should be pointed out that, according to this result, none of the upper and lower electronic states are in common with those of the known systems of Ag_2. The wave-lengths of the observed band heads, their estimated intensities, and the corresponding vibrational quantum numbers are listed in Table 1.

Table 1

λ	I	v',v''	λ	I	v',v''
2756·8	1	4 0	2825·4	8	1·2
2761·4	2	5 1	2828·6	5	2 3
2768·4	4	3·0	2839·8	4	0 2
2771·7	3	4 1	2842·7	5	1·3
2780·1	8	2·0	2845·6	4	2·4
2792·6	10	1·0	2849·3	2	3·5
2796·0	5	2 1	2856·4	1	0·3
2806·5	8	0 0	2861·9	2	2 5
2809·6	7	1·1	2866·7	2	3·6
2812·5	5	2 2	2873·3	1	0 4
2822·5	8	0 1			

Ruamps[3] designated the absorption system λλ2750–2850 as system $(B–X)$ of Ag_2, and suggested the values of its main molecular constants as: $\nu_e = 35{,}827{\cdot}3$ cm^{-1} ($\nu_{00} = 35{,}806{\cdot}1$), $\omega'_e = 151{\cdot}3$ and $\omega''_e = 192{\cdot}4$ cm^{-1}. Now, out of the nineteen bands observed by him, there are, within 0·5 Å, thirteen stronger ones having wave-lengths the same as ours. Hence his system and ours are undoubtedly one and the same system. The discrepancy in molecular constants appears to be due to the choice of the value of ν_{00}; that is, the (0,0) band. We find that with our choice the irregularity in the values of the vibrational quanta $\Delta G''$ is much less. From our results we believe that the fundamental frequency of vibration of the ground-state of Ag_2 is $\omega''_e = 207$ cm^{-1}, and not 192·4 cm^{-1} as is generally believed.

Three far ultra-violet systems. The three far ultra-violet absorption systems of Ag_2 observed in the regions λλ2640–2700, λλ2560–2620 and λλ2460–2560 and designated by Ruamps[3] as systems $(C–X)$, $(D–X)$ and $(E–X)$ are also found in discharge but with much fewer bands. Our emission bands attributable to the so-called system $(C–X)$ are:

2645·4(1,0), 2656·5(0,0), 2658·0(1,1), 2660·3(2,2), 2661·7(3,3), 2663·2(4,4), 2665·2(5,5), 2666·8(6,6), 2668·7(7,7), 2674·9(10,10).

Our emission bands attributable to the system $(D–X)$ are:

2562·4(0,0), 2564·2(1,1), 2566·0(2,2), 2568·0(3,3), 2570·0(4,4).

Our emission bands attributable to the system $(E–X)$ are:

2481·9(1,0), 2485·2(2,1), 2488·1(3,2), 2490·6(0,0).

Besides the aforementioned bands of Ag_2, eight persistent bands of SiO have been detected as very weak bands in the region λλ2290–2590. Of course, lines of silver and neon were also present in the working ranges of the different systems. Fortunately they were not present in great number.

In conclusion, our work on the emission band systems of Ag_2 reveals: (1) the existence of one new system in the region λλ3150–3630; (2) all the known absorption systems have their counterparts in emission; (3) the fundamental vibrational frequency of Ag_2 is 207 cm^{-1} and not 192·4 cm^{-1} as is generally believed; (4) the existence of vibrational perturbation and predissociation in the emission system λλ4100–4700.

MONTE CARLO MODEL OF A FRACTURE PROCESS

By Prof. C. C. HARRIS

Henry Krumb School of Mines, Columbia University in the City of New York

During the course of an investigation of the role of energy in comminution[1], a model of an elementary random fracture process was investigated with the view of illustrating some of the probability aspects of size reduction. Particles are subjected to events in which stresses are applied and released successively. The magnitude of the stresses and the specific energy (energy per unit volume of particle) which they generate are statistically distributed. In the simplest case, the particles are identical and they fracture if the specific energy, E, equals or exceeds a certain threshold level, E_f. After fracture, the fragments leave the stress field under consideration for a subsequent operation and the stresses are brought to bear on a fresh particle. If fracture does not occur during an event (that is, $E < E_f$) the strain energy is assumed to be dissipated and the particle remains in the stress field until fracture occurs. In reality, E_f is also distributed statistically, but for the present it will be assumed constant. Also it would be more realistic to postulate that some breakage occurs with values of E just below E_f, but is insufficient to reduce the size of the particle significantly; catastrophic failure occurs when $E \geqslant E_f$. If E_f is near to the maximum value of E, the curve frequency of fracture versus energy requirement will be severely skewed in a positive direction, indicating much wasted energy; the form of this relationship was required.

It is assumed that the specific energy imparted by the events is distributed rectangularly and takes integral values from 1 to 10 arbitrary units, each integer occurring in a random sequence with equal probability. Tables of random numbers (counting zero as 10) provide values of E. The energy consumed until a particle fractures is given by the sum of N digits along rows or columns between two values of $E \geqslant E_f$ and including the second value. Tabulation of results showed number of events necessary to cause breakage, N; E_f and $\Sigma^N E$. An extract from tables is: 9 0 3 7 4 8 6 3 1 1 5 5 8, which for $E_f = 8$ tabulates as:

N	E_f	$\Sigma^N E$
1	9	9
1	10	10
4	8	22
7	8	29

2,240 consecutive digits[2] were treated in this manner, producing 650 fractures; the total number of eights was 227; of nines, 216; of zeros, 207. Because the probability of occurrences of any digit is 0·1, each is expected to appear 224 times in a sequence of 2,240; thus, the particular extract of the random number tables sampled in this work was somewhat deficient in 9's and 0's. The entire assembly of data analysed into frequency, according to number of events and energy input to cause fracture, is shown in Fig. 1. Also given are theoretical and experimental averages; in all cases the agreement is good.

By evaluating the various permutations of digits 1 to 9 and 10 in summing to give integers 8, 9, 10 . . ., the probability of the entries in Fig. 1 can be calculated. In particular, the sudden decrease in frequency of occurrence when particles require eleven energy units for fracture can be confirmed; this is because at least two events are now necessary to cause fracture. The expectations of 10, 11, 12 and 13 are, respectively, 0·121 × 672 = 81·4, 0·0331 × 672 = 22·2, 0·03641 × 672 = 24·5, and 0·040051 × 672 = 26·9. These are near to the values obtained by the Monte Carlo procedure; improved expectation estimates can be obtained by using the experimental value 650 instead of 672. In the same manner, the other expectations can be obtained, but the calculations become unwieldy as energy requirements increase; however, it is clear that the probabilities for the higher values of N are vanishingly small, being of the order of 10^{-N}. The two-stepped lines give the limits for the formation of integers from the sum of N digits. The upper line is given by $10 + 7\,(N-1)$, while the lower line is $8 + (N-1)$; the average, $9 + 4\,(N-1)$, provides a good fit to the experimental averages of N.

The analysis in Fig. 1 illustrates the reason for the uneven nature of the frequency versus energy distribution; it is composed of the sum of a series of simple distributions, each for a particular value of N. If E was graded into smaller intervals, the curve would be expected to smooth out. The analysis has been extended by dividing the data into three sets depending on whether the *coup de grâce* was delivered by an 8, 9 or 10; these are generally similar with only local random differences. Such a detailed analysis would be of importance in relating energy input to fragment size, because the strength of the dispatching blow will determine the resulting size distribution.

It is to be emphasized that this aspect of the comminution process is not primarily concerned with the production of fine material, but rather with coarse size-reduction. Here, for maximum effect, the objective should not be to bring to bear as much stress as possible, but rather to limit the stress to that only just necessary to cause fracture; general considerations show that, as expected, more effective energy utilization would result if the spectrum of E were reduced below and above E_f. It is of interest that in slow compression, which is a relatively efficient comminution process, E is steadily increased to E_f as a maximum value.

As already pointed out, the results of the present model can be calculated from elementary probability theory. A number of refinements can be suggested which, while providing a more realistic model, would, however, make direct calculation too involved. (*a*) Increase the

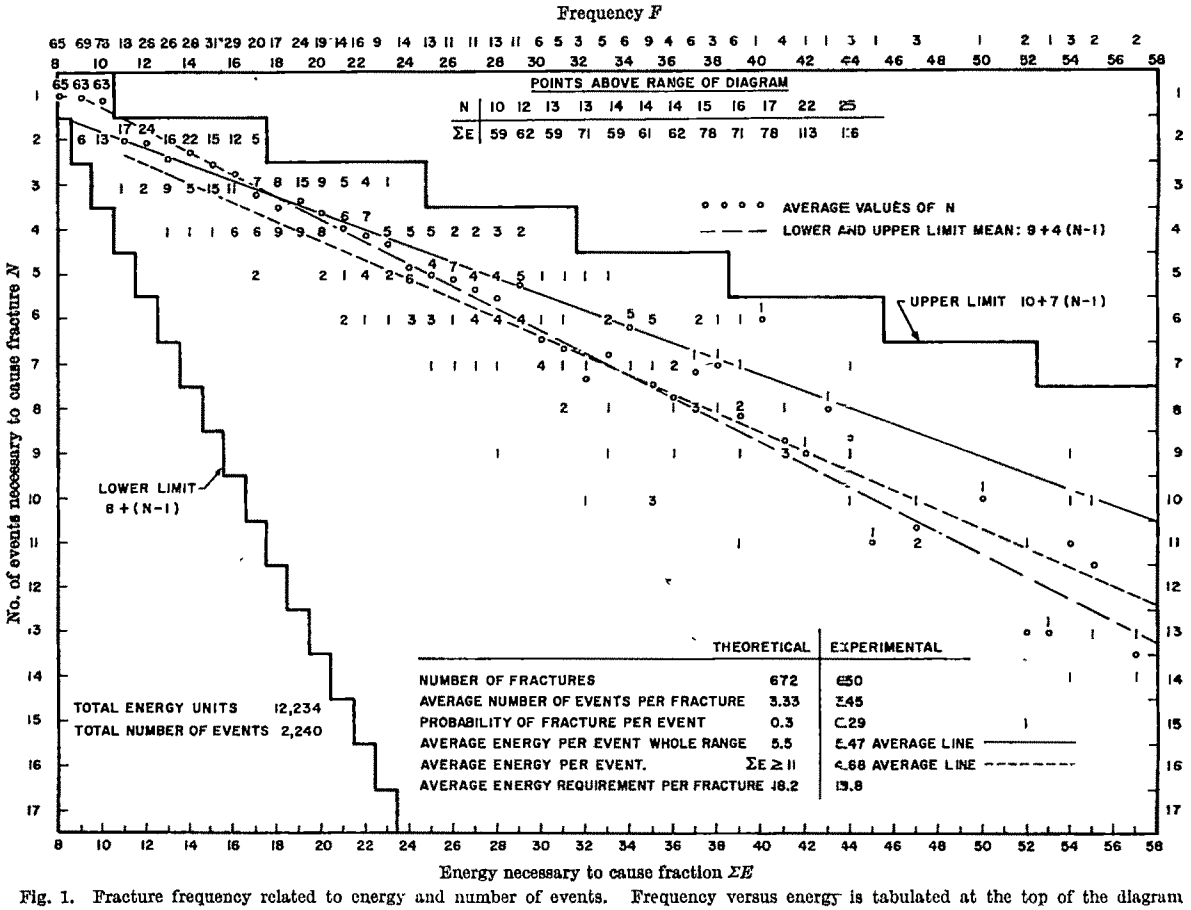

Fig. 1. Fracture frequency related to energy and number of events. Frequency versus energy is tabulated at the top of the diagram

intervals by which E progresses. An obvious procedure would be to cover the range 1–100 arbitrary units; this should smooth the frequency-energy distribution curve. (*b*) Incorporate fatigue into the particle characteristics; for example, they might fracture after, say, the tenth event irrespective of the magnitude of the blow sustained. Or, alternatively, E_f may diminish with each unfruitful event. (*c*) The strength of the particles may be distributed randomly; this can be obtained by allotting values of E_f from a second table of random numbers. (*d*) The distributions may be other than rectangular. (*e*) If fracture does not occur during an event, only a portion of the strain energy may be dissipated. In all these cases effective solution would require a digital computer to carry out essentially the same procedure as that described here.

Finally, although this model was devised in order to investigate an elementary comminution process, it appears appropriate to systems, inanimate and animate, where the fundamental unit responds only when the magnitude of the externally applied stimulus reaches a threshold value, both of these values being distributed statistically.

PALAEOGEOGRAPHY OF THE TORRIDONIAN APPLECROSS GROUP

By GEORGE E. WILLIAMS

Sedimentology Research Laboratory, Department of Geology, University of Reading

THE Precambrian Torridonian sediments overlie the Lewisian Gneiss along the north-west coast of Scotland from the Inner Hebrides to Cape Wrath (Fig. 1). Strata are low-dipping, often nearly horizontal.

The sub-Torridonian gneiss surface. Detailed work in the Cape Wrath area reveals that, with rare exceptions, the sub-Torridonian surface is thoroughly decomposed to depths of 3 m and closely parallels the major bedding planes of the overlying sediments. Local etching and exfoliation of the surface suggest that the weathering occurred in Torridonian times. From Quinag southwards, however, the unconformity is highly irregular and the gneiss little weathered. At Quinag, arkoses overlap a hill at least 300 m high, and at Loch Maree the pre-Torridonian relief reached about 600 m (ref. 1).

Torridonian stratigraphy. The Torridonian has been divided into three groups[1] (Table 1).

Table 1. MAJOR DIVISIONS OF THE TORRIDONIAN

Group	Approximate thickness in m	Lithology
(3) Aultbea Group	900 to 1,400 in Coigach	Sandstones, flags and grey shales passing down into red sandstones and grey flags with shaly partings.
(2) Applecross Group	450 at Cape Wrath; 1,800 to 2,400 in the Gairloch-Torridon area.	Red arkoses and conglomerates with numerous pebbles of quartz, quartzite, jasper, chert, felspar porphyry, etc. Occasional red shales. Local basal breccias
(1) Diabaig Group	15 at Quinag; 150 at Gairloch; 3,000 in Skye:	Sandstones and grey mudstones with rippled sandy lenticles. Basal breccias and boulder beds of local origin. In Skye, dark grey sandy shales and buff grits passing down into epidotic grits with occasional purple and green shales

Except in Skye, the Diabaig Group generally occurs in the low-lying areas between pre-Torridonian hills and mountains. The breccias probably represent locally derived screes[1]. The mudstones at Diabaig have been compared with ordinary shallow-water marine sediments, including intertidal deposits[2]. The group gradually thickens from 150 m at Gairloch to 3,000 m in Skye[1,3]. No Diabaig sediments occur north of Quinag.

The Applecross Group contains sub-rounded to rounded pebbles, tabular conglomerates, large-scale trough and planar cross-stratification, channel-forms, occasional small-scale ripplemarks and rare desiccation-cracked red shales. The sediments are comparable with those of modern braided streams[4] and alluvial fans[5]. The group thickens from 450 m at Cape Wrath to 1,800–2,400 m in the Gairloch–Torridon area. Mean grain size gradually decreases southwards. Concomitantly, maximum diameter of the pebbles decreases from about 180 mm at Cape Wrath to 50 mm at Applecross[1].

The upper Aultbea Group at Cailleach Head, comprising grey, occasionally desiccation-cracked shales and interbedded rippled, cross-stratified and laminated sandstones, suggests a shallow (intertidal ?) environment not unlike that postulated[2] for the Diabaig mudstones. The lower Aultbea sandstones may represent the transition from braided stream to shallow marine environment.

It is generally accepted that the three groups form a conformable sequence. However, at Stoer (grid ref. 042330) thick-bedded Applecross conglomerates and arkoses overlie atypical Diabaig red sandstones and shales with slight angular unconformity, the lower beds having been tilted slightly to the north-west prior to Applecross deposition. The contact is marked by a line of sandstone boulders derived from the underlying rocks. Hence the Diabaig Group includes strata much older than the Applecross sediments.

The age of the red breccio-conglomerate at Stornoway is uncertain[7]. However, the poorly consolidated nature of the deposits and boulders of Torridonian-like pebbly arkose in the basal beds at Swordale suggests a post-Torridonian age.

The Applecross Group. Detailed investigation of the unconformity and sediments northwards from Quinag suggests that this area holds the key to the regional palaeogeography of the Applecross.

At Cape Wrath the sediments are best divided stratigraphically into five facies (Table 2). The progressive upward fining and concomitant change of bedding character suggest a change in the depositing streams from conditions of predominantly

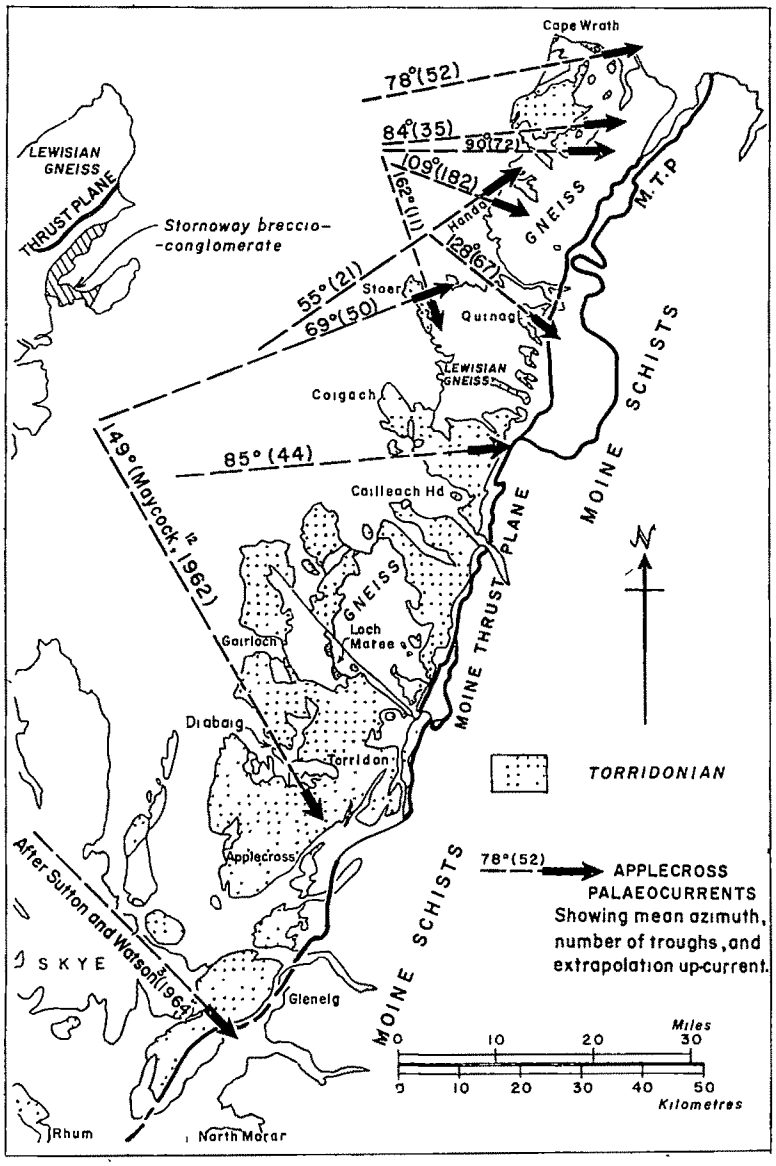

Fig. 1. Locality map, showing general geology and palaeocurrent directions determined from the Applecross Group

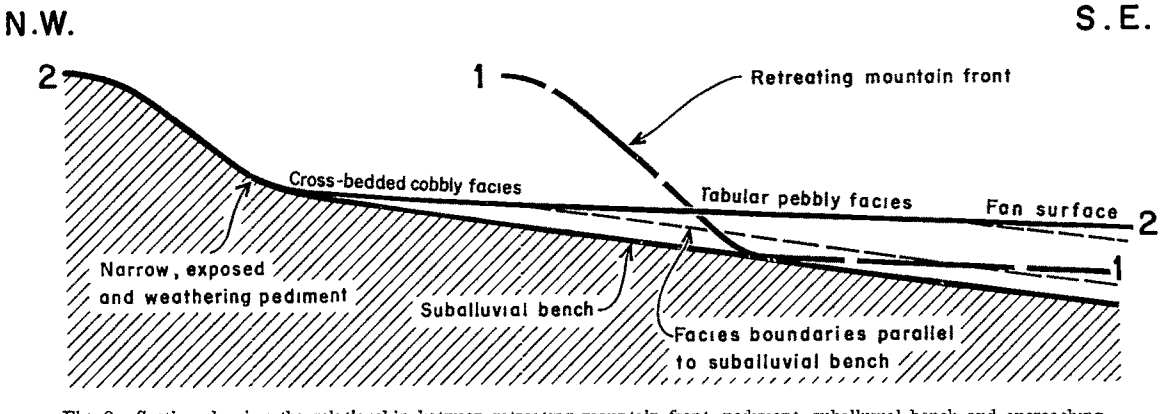

Fig. 2. Section showing the relationship between retreating mountain front, pediment, suballuvial bench and encroaching alluvial fan

rapid or shooting flow of the upper flow régime to those of predominantly tranquil flow of the lower flow régime[6]. Facies 5 is similar to the type Applecross sediments south of Loch Torridon. The vertical variations in the Cape Wrath sequence thus seem to reflect the lateral variations within the group as a whole.

Palaeocurrents. Palaeocurrent data from the Applecross Group are strongly unimodal. Each current direction was taken as the arithmetic mean of the azimuths of numerous trough axes exposed on nearly horizontal bedding surfaces. Regionally, the current pattern (Fig. 1) is more complex than has hitherto been assumed[7]. Although mean derivation from the north-west or west-north-west is now confirmed, the radiating arrangement of the currents suggests two large, coalescing fans. Coalescence appears to occur in the Coigach-Handa area, where the lower beds have been derived from the north-west and upper beds from the south-west.

Palaeogeography. Lithology, sedimentary structures and palaeocurrents suggest a piedmont or alluvial fan environment for the Applecross Group.

The flat, weathered gneiss surface beneath the sediments north of Quinag is interpreted as a buried pediment or suballuvial bench. This was formed at the foot of a north-westerly retreating elevated source area and progressively buried by the encroaching alluvial fan (Fig. 2).

All facies boundaries are diachronous and parallel to the suballuvial bench surface, dipping gently away from the base of the mountain front. The resulting upward fining of the sediments above the bench reflects the radial variation on the fan surface. As long ago as 1915, Lawson[8] postulated this relationship between an elevated source area, its flanking pediment and alluvial fan apron, and the planar rock surfaces commonly observed beneath dissected alluvial fans in south-western United States.

Relative uplift of the gneiss immediately north-west of Quinag probably initiated pediment formation and alluviation. It is noteworthy that north-east–south-west normal faulting is common in this area.

As the suballuvial bench must be intimately associated with the source area of the sediments, its weathered profile has been extensively studied. In the weathered gneiss, from 50 to 100 per cent of the plagioclase felspar has been altered to sericite and illite, haematite has partly replaced biotite, and hornblende has been entirely altered to sericite and chlorite. Microcline is only slightly weathered. It is clear that such a weathering of the Lewisian Gneiss could have supplied the microcline-rich arkoses and haematitic, illite-rich siltstones and shales constituting most of the Applecross Group. It also accounts for the almost total absence of locally derived basal breccias north of Quinag. The deep weathering of the bench and the abundant evidence for fluvial deposition of the sediments above suggest a warm, humid climate.

It seems likely that frequent sheetfloods on the upper portions of the fan deposited the tabular conglomerates of facies 2. The interbedded arkoses of this facies suggest a channel environment, occasional point-bar deposits indicating that stream migration was mainly away from the fan median. Progressively finer sediments accumulated downslope, probably as the channel and overbank deposits of braided streams.

Preliminary calculations based on slight vertical variations in palaeocurrent direction suggest: (1) the apex of the fan migrated approximately 40 km west-north-westwards during deposition of the Cape Wrath sequence; (2) a mean angle of slightly less than 1° between suballuvial bench and fan surface. Transport distances for each facies can also be calculated by this method.

Fig. 3 shows the relationship between the sediments astride the suballuvial bench and the remainder of the Applecross. This accounts satisfactorily for the lateral and vertical variations within the group, the palaeocurrents, the sudden change in structure of the sub-Torridonian surface, and the absence of Diabaig sediments north of Quinag.

Disturbed bedding of the Applecross Group. Disturbed bedding is abundant in facies 5 at Cape Wrath and the Applecross sediments south of Quinag. Structures include: (1) undulose and hazy bedding planes; (2) convolute bedding; (3) overturned and deformed cross-strata; (4) large-scale cuspate and diapiric structures. These structures probably formed *in situ* by the shifting and rearrangement of quicksands[9].

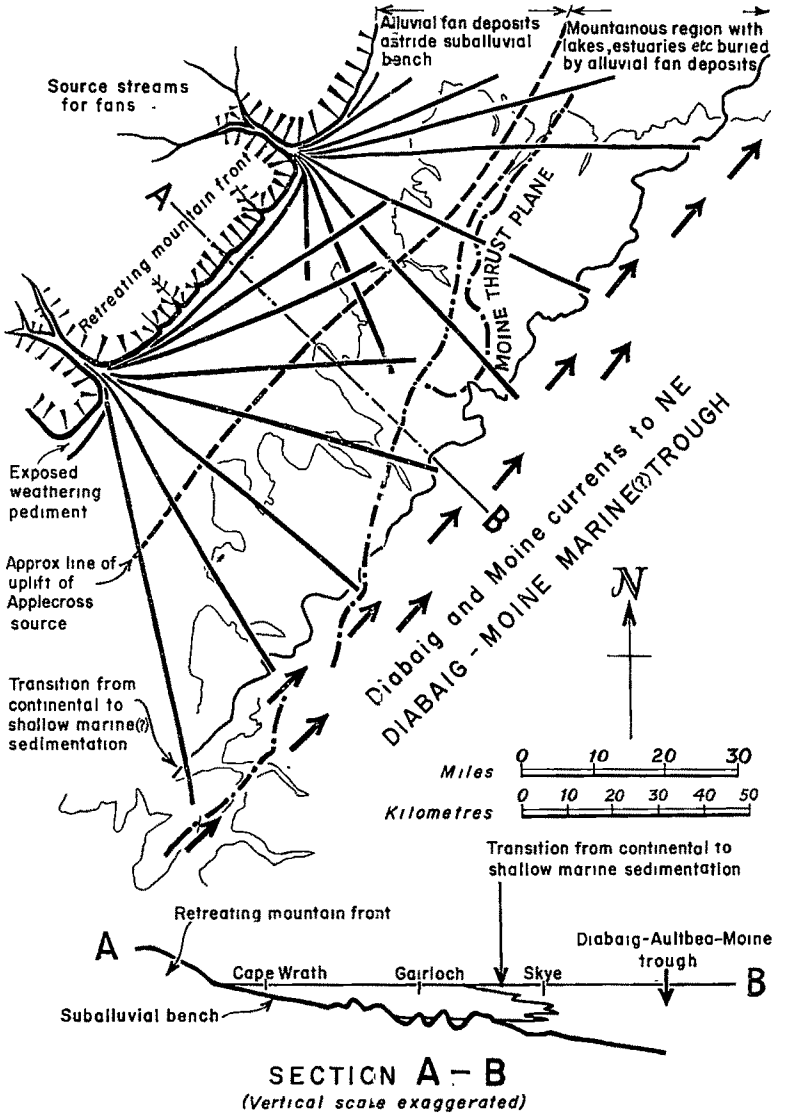

Fig. 3. Suggested palaeogeography of north-west Scotland in late Torridonian times

Table 2. Subdivisions of the Applecross Group at Cape Wrath

Geological survey divisions[1]	Facies	Main characters	Approximate thickness in m
t'''	(5) Contorted sandy* facies	Cross-stratified and tabular pink and grey arkoses; subordinate red fine sandstones and silty shales, rare gravelly bands with pebbles up to 50 mm in diameter. Channel-forms common. Ubiquitous disturbed bedding. Occasional small-scale ripplemarks.	90+
	(4) Cross-bedded sandy facies	Cross-stratified and tabular pink and grey arkoses, with occasional shale and conglomerate bands. Channel-forms. Disturbed bedding common near top of division Occasional small-scale ripplemarks.	90–120
t''	(3) Cross-bedded gravelly facies	Dominantly cross-stratified red felspathic gravels and arkoses; interbedded tabular gravels and conglomerates Channel-forms Disturbed bedding and ripplemarks rare.	90
	(2) Tabular pebbly facies	Flat-bedded red conglomerates up to 4 × 200+ m in section, grading down into or alternating with cross-stratified red felspathic gravels and arkoses. Channel-forms.	100–150
t'	(1) Cross-bedded cobbly facies	Cross-stratified and tabular red conglomerates, felspathic gravels and arkoses. Cobbles up to 180 mm in diameter. Channel-forms common.	0–30

* Wentworth grade scale terms used, except gravel (2–4 mm).

Thus quicksands probably were abundant on the outer portions of the Applecross alluvial fans. Water infiltrating into the coarser materials at the heads of many modern alluvial fans moves down the fans under hydrostatic head, often rising as springs at the fan margins[10,11]. By analogy, it is suggested that the bedding disturbances of the Applecross Group occurred in quicksands downslope from the water table-fan surface junction. The large diapiric and cuspate structures may have been caused by rising springs.

Bands and patches bleached light grey are common in the upper 120 m of the Cape Wrath sequence and have been noted in the Applecross to the south. Evidence suggests that the bleaching occurred shortly after deposition of the sediments. A moderately reducing environment seems likely, possibly promoted by a high, fluctuating water table.

The connexion between the Torridonian groups and the Moine Schists shown in Fig. 3 is based on Sutton and Watson[3]. The proposed lines of facies variation run obliquely to the present elongated outcrop of the Torridonian. Correction for post-Torridonian faults may alter these regional trends slightly.

Further work is necessary before the palaeogeographic picture is complete. However, it is hoped that this preliminary report has demonstrated the important connexion between geomorphic processes and contemporaneous sedimentation.

I thank my colleagues for helpful discussion and advice.

DEPOSITIONAL ENVIRONMENT OF BRITISH LIASSIC IRONSTONES CONSIDERED IN THE CONTEXT OF THEIR FACIES RELATIONSHIPS

By Dr. A. HALLAM
Grant Institute of Geology, University of Edinburgh

ALTHOUGH the petrology of the economically exploitable oolitic ironstones in the British Lias has been intensively investigated and their conditions of formation repeatedly discussed[1–5], a number of outstanding problems still remain. It is believed that some of these can be resolved by studying the ironstones in the context of their facies relationships. It will be shown in addition how this approach facilitates the interpretation of early Jurassic palaeogeography.

The ironstones are typical minette ores and consist characteristically of chamosite ooliths, sometimes altered to limonite, in a sideritic and chamositic matrix, although numerous minor variants occur. For full petrographic details Taylor's monograph[6] on the lithologically similar Northampton Sand ironstone (Middle Jurassic) remains indispensable.

As indicated in Table 1, ironstones are widely distributed in the British Lias, being missing only from the Hettangian and Carixian stages. All are well known except the Ardnish Ironstone near Broadford, Skye, a 2 ft. band which was only recently discovered[7]. The most important ironstones in western Europe are the minette ores of Lorraine, ranging in age from Upper Toarcian to Bajocian (that is, 'Aalenian'); others occur in the Lower Sinemurian and Carixian of north-west Germany and the Carixian of Bornholm. Thin beds containing chamosite or limonite ooliths occur widely and include two in the Hettangian of Baden-Württemberg, the *Psilonotenbank* and *Oolithenbank*. It is evident, therefore, that in north-west Europe as a whole conditions suitable for minette formation occurred locally throughout the Lias.

Table 1

Stage	Scotland	Yorkshire	Midlands
Toarcian	Raasay	Rosedale	
Domerian or Upper Pliensbachian		Cleveland	Marlstone
Carixian or Lower Pliensbachian			
Sinemurian	Ardnish		Frodingham
Hettangian			

Facies Relationships

The extent to which the Liassic ironstones represent condensed deposits has not always been fully appreciated in discussions of their origin. As indicated in Fig. 1 the lateral equivalents of the ironstones in sandstones or shale are substantially thicker. Even this does not give an adequate picture of the extent of condensation, since

allowance must be made for post-depositional compaction of the shales. Furthermore, although the Yorkshire coast Liassic succession is one of the thickest in Britain, it still only signifies a moderate rate of sedimentation. Thus the Toarcian shales of the Nordoldenburg Trough in north-west Germany are some 400 m thick[8], about the same as the whole Liassic succession in Yorkshire.

Stratigraphical control for the correlations given in Fig. 1 is good and there is no likelihood of major non-sequences except possibly in the case of the Raasay Ironstone. (This last case has been allowed for so far as possible by correlating the ironstone only with the *commune* sub-zone of the *bifrons* Zone, though it may well span a much longer period of time[9].) On the other hand, it is likely that brief periods of erosion alternated frequently with periods of slow deposition.

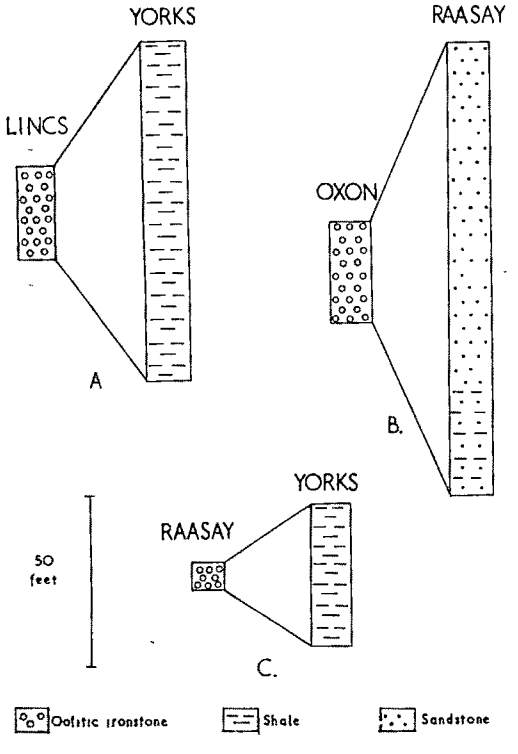

Fig. 1. Diagram to illustrate the condensed nature of oolitic ironstones compared with their lateral equivalents in shale and sandstone: *A*, Frodingham; *B*, Marlstone; *C*, Raasay

Brockamp[10] has observed that the German ironstones often occur at the boundary between sandstones and shales; a comparable association is characteristic of British Liassic ores. Both the Frodingham and Cleveland ironstones pass laterally into silty and sandy shales and the Rosedale and Marlstone ironstones pass laterally into fine sandstones. The lateral equivalents of the more poorly exposed Raasay and Ardnish ironstones are not known, but both beds occur in a sequence of silty and sandy shales.

In considering the general problem of iron enrichment in the sea-water or bottom sediment it is misleading to restrict attention, however, to the chamosite/limonite oolites. This is made evident by examining the facies relationships of the Cleveland Ironstone on the Yorkshire coast. Abundant ammonites allow a detailed correlation from the ironstone in a fairly normal, partly oolitic development near Staithes to its lateral equivalent a few miles to the south-east of a thicker sequence of silty/sandy shales with thin nodule bands of non-oolitic siderite mudstone (Fig. 2). It cannot be seriously supposed that the chemical constitution of the sea-water differed appreciably over such a short distance. Therefore it follows that the concentration of iron in the beds to the north-west, sufficient to make an exploitable ore, is the result of local physical conditions (a higher terrigenous sedimentation rate to the south-east in quieter and probably slightly deeper water). Although, considering the shales in bulk, the iron content is considerably diminished, it has been concentrated in the nodules owing to diagenetic segregation.

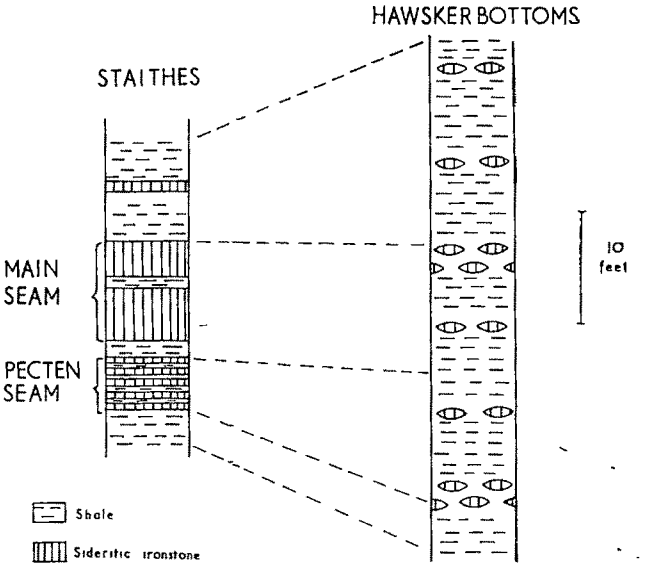

Fig. 2. Correlation of the *spinatum* Zone on the Yorkshire coast, based on Howarth (ref. 21). The Cleveland Ironstone at Staithes comprises the Main and Pecten seams

Obvious as the foregoing deduction may appear, it is nevertheless significant since the facies of silty/sandy shales with sideritic nodules is much more widespread in the Lias than the chamosite oolites. For example, in Yorkshire this facies begins just below the base of the Carixian and continues up to the top of the Domerian. There is a return to normal non-silty calcareous facies in the lower part of the Toarcian but the silty/sandy ferruginous facies returns in the Upper Toarcian.

In the Midlands and South-west England, in contrast, the Lower Lias is largely free of ferruginous beds, the most notable exception being the Lower Sinemurian Frodingham Ironstone in north Lincolnshire. However, the Lower Domerian, that is, the zone preceding that containing the Marlstone and Cleveland ironstones, is marked by a great spread of silty shales with sideritic nodules over most of this region. Apart from the local occurrence of diachronous sandy beds in parts of the south-west, the Toarcian marks a return to normal calcareous clay deposits.

British Liassic rocks can in fact be divided into two distinctive associations which may be termed the 'calcareous' facies and 'ferruginous' facies. The former is the more widespread and consists of argillaceous deposits and limestone. Smooth-textured shales, clays or marls with strongly sub-ordinate detrital quartz of silt grade and subsidiary layers and nodule bands of fine-grained argillaceous limestone were probably deposited in slightly deeper and quieter off-shore waters. Shallower near-shore deposits, as seen in Glamorgan, the Mendips and the Inner Hebrides, contain a higher proportion of limestone, which includes oolitic and bioclastic varieties.

The argillaceous rocks of the ferruginous facies are typically rich in detrital quartz of silt to fine sand grade (on the Wentworth Scale). This gives them a distinctive rough texture, while the abundant muscovite flakes produce a characteristic glint. The associated sideritic nodules correspond to the calcitic nodules in the calcareous clays just as the chamosite oolites may be thought of as the equivalents of the calcareous oolites. Calcareous nodules may also occur, however, though not in intimate association with the sideritic.

Sandstones are subordinate in both facies, although commoner in the ferruginous; they are almost invariably fine grained. Whereas those in the calcareous facies are well sorted, in a calcitic cement (for example, in the Lower Broadford Beds of the Skye area) the sandstones in the ferruginous facies are of several types. One type, well exemplified by the sandstones at the Carixian–Domerian boundary in Yorkshire, is well sorted and clean-washed, with a calcitic cement as in the calcareous facies. Other sandstones, though possessing a calcitic cement, contain limonite associated with the quartz grains (for example, the Upper Broadford Beds sandstones of the Skye area). A third type, strictly confined to the ferruginous facies, consists of intimate mixtures of clay and fine sand. The lithological contrast allows the recognition of mottling exhibiting several varieties of trace fossil including *Chondrites*, *Diplocraterion*, *Rhizocorallium* and *Thalassinoides*. Good examples include the topmost Sinemurian and the topmost Toarcian beds on the Yorkshire coast, and much of the Pliensbachian in the Inner Hebrides.

Bearing of Facies Relationships on Hypotheses of Ironstone Formation

The abundance and diversity of benthonic fossils in dominantly argillaceous sediments signifies a widespread sedimentary environment of quiet but shallow-water marine conditions in the British area during Liassic times, and implies that the associated landmasses were of very subdued relief. In the context of this environmental picture the occurrence of mixed sandy, silty and argillaceous rocks is likely to signify the proximity of rivers. Tidal and longshore currents are of course capable of transporting sand by traction considerable distances from river mouths but the deposits that result from such transportation are normally well sorted—mud and fine silt having been winnowed out. The mixed sand, silt and clay deposits that occur in the ferruginous facies have evidently been buried before any major winnowing action could occur. Such mixed deposits, lacking any trace of lamination because of the activity of burrowing organisms, are characteristic of the distal parts of pro-delta régimes of the present time[11,12]. In support of this interpretation, fossil driftwood appears to be more abundant in the ferruginous than in the calcareous facies of the Lias, due allowance being made for variations in rates of sedimentation. We must now consider the bearing of this interpretation on the various hypotheses of ironstone formation.

The orthodox views of minette ore formation all assume derivation of iron by continental weathering, although opinions differ on the mode of transportation and concentration on the sea bed. A radically different hypothesis has been proposed recently by Borchert[13,14], who believes that the conventional interpretation has several insuperable difficulties and argues that certain deposits on the sea floor, possibly far from land, themselves acted as sources of iron. Though Borchert's ideas were received with some scepticism in the discussion following the reading of his paper in London[15], they were treated sympathetically by Dunham[5] as being possibly valid in the case of certain Liassic ironstones.

It will be convenient to consider Borchert's hypothesis first. He envisages three depth zones in the sea with distinctive chemical characteristics and bottom deposits. The deepest is the hydrogen sulphide zone, characterized by anaerobic bottom waters and sediments consisting of pyritic bituminous mud. The shallowest is the oxygen zone, with a rich bottom fauna, where limonitic ooliths form in agitated water. Between these is the carbonic acid zone, rich in carbon dioxide, where the bottom deposits consist of sideritic muds; iron is supposed to be mobilized from the deposits of this zone. Part of the iron is carried by marine currents into shallower water where it contributes to the formation of limonite. Part is carried towards the hydrogen sulphide zone, where it encounters silica dissolved in alkaline water liberated from the bituminous mud; as a result chamosite forms.

A major difficulty of Borchert's interpretation is that the depth zones and chemical reactions are hypothetical so far as marine conditions are concerned. There is no evidence, for example, of a widespread carbon dioxide zone in seas of the present day where the deeper water is anaerobic. Apart from this, however, these are ample grounds for rejecting his hypothesis for the Liassic ironstones.

The necessary association of ironstones and bituminous shales at the same stratigraphic horizon exists nowhere in western Europe. On the contrary, there is a clear negative correlation, since laminated bituminous shales, such as occur in parts of the Hettangian and Sinemurian of South-west England and the Lower Toarcian of a much more extensive area, invariably belong to the calcareous facies. Borchert actually argues for deep-sea stagnation and bituminous facies on the grounds that, in the absence of polar ice caps during periods of ironstone formation, deep oceanic circulation would be far more sluggish than to-day. Liassic deposits occur in the Mediterranean region (Ammonitico Rosso facies) which were probably laid down in deeper water than anything in north-west Europe; they are, however, strikingly deficient in organic matter and are not especially rich in iron.

The evidence from facies associations lends support in fact to the conventional view of iron derivation, with ferruginous deposits forming close to river deltas. We must now examine briefly certain ideas on the site of ironstone deposition and the transportation and concentration of the iron, in so far as they are pertinent to the Liassic ores.

It has been suggested that ironstones formed close to old shorelines[10,16]. This is not necessarily so. The unequivocal shoreline deposits of Glamorgan and the Mendips are in calcareous facies and include normal oolites and skeletal limestone, as do the near-shore deposits of the Lower Broadford Beds in Skye. In contrast, none of the oolitic ironstones are obviously associated with an old shoreline, though because of inadequate exposure this cannot be decisively ruled out. It has been pointed out, moreover, that certain Asiatic rivers have been observed to carry iron-bearing sediments far into the open sea[17].

Another common belief is that the ironstones did not form in the open sea but in some sort of near-shore lagoon. To be meaningful, the term lagoon should be restricted to partly isolated regions of abnormal salinity, or at least regions protected from strong wave- or tide-induced water disturbance. The Liassic ironstones contain abundant benthonic fossils including many stenohaline types, with no suggestion of abnormal salinity. There is in addition abundant evidence from the rocks themselves of strong water agitation.

Two different solutions have been proposed to account for the rarity of detrital quartz grains in what are evidently shallow-water deposits that have been subjected to agitation sufficient to transport such grains. Hemingway[8], influenced by an approximation in the Yorkshire Lias on three occasions to a cyclic sequence of shale–sandstone–ironstone, has related the sedimentation to erosional cycles on the land. As the latter became peneplaned, mechanical erosion diminished so that finally only chemical

derivatives including iron were transported and deposited in shallow restricted arms of the sea. This hypothesis fails to account for the frequent lateral passage of ironstones into clastic rocks and is clearly incompatible with the interpretation adopted in this article. Some sort of 'clastic trap'[18] seems a more plausible explanation. That is, some iron was transported slightly beyond the limit of deposition of the bulk of the terrigenous sediments. We turn now to how this might have been achieved.

The problem of the transportation and concentration of iron to form exploitable ores is singularly acute because of the lack of modern analogies. As is well known, chamosite is apparently forming nowhere in recent marine sediments and siderite is rare, while the concentration of dissolved iron in sea-water is negligible. The most commonly held belief is that the iron was transported in rivers in the ferrous state protected by organic colloids and later deposited on entering the alkaline environment of the sea. Carroll[19] has recently put forward a different suggestion, pointing out that ferric oxide can travel to the sea as particles coating the surface of clay micelles and can be removed by a lowering of the redox potential to negative values, which converts the ferric iron into the more soluble ferrous form. She argues that chamosite may be formed in such a reducing environment by the interaction of iron released in this way with kaolinite.

It seems quite probable that siderite could form as a result of the process Carroll describes, iron released from clay minerals within silty pro-delta muds reacting with carbonate ions in the interstitial water and afterwards segregating to form nodules. In support of this, there is a clear association of siderite with clay in the Lias. Those sandstones in the ferruginous facies which have been winnowed free of clay particles, such as the Marlstone 'sandrock' in Leicestershire and the *davoei-margaritatus* Zone sandstones of Yorkshire, are cemented by calcite not siderite, suggesting that iron has been removed with the clay.

Unfortunately Carroll's interpretation does not solve the problem of chamosite concentrations. All the normal Liassic clays studied by me consist dominantly of illite, kaolinite being markedly subordinate. Yet chamosite is the most abundant clay mineral in the ironstones. The influx of large quantities of illite, just as with detrital quartz, evidently diluted the available iron to such an extent that exploitable ore could not form. Therefore in a sense we are back where we started. It is hard to resist the conclusion that some iron was carried, perhaps as a colloidal solution or suspension, beyond the area where most of the terrigenous sediment was deposited. It could only concentrate on the sea bottom in areas of extremely slow sedimentation, probably off-shore shoals. Chamosite presumably formed authigenically in a reducing environment within fine-grained sediment but was evidently stable in slightly oxidizing conditions, as testified by the rich benthonic fauna Presumably it was carried to the surface by burrowing organisms and ooliths produced as a result of water agitation. Planktonic organisms such as diatoms could well have contributed to both the iron and silica required for the formation of chamosite, since opaline silica is readily soluble within sediments.

As regards the difficulty concerning the lack of modern analogies, one should bear in mind the following point. Because the world to-day has abnormally high relief terrigenous sedimentation rates on the continental shelf in the vicinity of river deltas are probably a good deal higher than in the shelf sea that covered north-west Europe in the early Jurassic. The concentration of iron coming from rivers need not have been appreciably higher than to-day, so long as sedimentation rates were slight. A comparison with the phosphate deposits that have formed recently off southern California may be apposite; these seem to owe their origin essentially to a conjunction of two factors: (*a*) a slow rate of sedimentation, (*b*) phosphate enrichment in sea-water due to upwelling. The significant point is that even in areas of upwelling phosphate concentration remains low compared with many other ions.

The well-known fact that iron concentrations in rivers are generally much higher than in the sea suggests that much may be deposited not far from the deltas. It would be instructive if studies could be made comparing the interstitial water composition of certain pro-delta and river-distant sediments.

Interpretation of Jurassic Palaeogeography

Distinction of the calcareous and ferruginous facies, and recognition of the probable association of the latter with river deltas, brings out with unexpected clarity important regional similarities and differences in the English Lower and Middle Jurassic. South-west England and Yorkshire show parallel contrasts during this time. The former area remained consistently within the calcareous facies, deeper water clays and calcilutites passing upwards stratigraphically into shallower water calcareous oolites. The Yorkshire Lias exhibits the first hints of a river delta near the base of the Carixian. Following a major marine transgression in the Lower Toarcian[20], when the calcareous facies temporarily returned, the pro-delta facies spread once more. In Middle Jurassic times, owing to shallowing of the sea as in the south-west, the delta itself began to cover the area. The Midlands form an intermediate area. In the Middle Jurassic, several oscillations are seen between calcareous facies (Inferior and Great Oolite limestones) and ferruginous/deltaic facies (Northampton Sand ironstone, Lower and Upper Estuarine Series), bound up possibly with the periodic migration of delta distributaries.

Major rivers evidently did not enter the sea in the area of South-west England, except locally for a short time during the Toarcian. It is tempting to suggest that the Yorkshire delta spread from a river draining the Scandinavian landmass (there is no good evidence supporting a Pennine landmass at the time, as shown in some palaeogeographic reconstructions). The main evidence favouring this is as follows. The only early Mesozoic remnants in Scandinavia are deltaic and ferruginous shallow marine deposits of Rhaetic and Lower Lias age. Also, most of the sandy deposits that spread into the north-west German Basin in Bajocian times came from the north or north-east[8]. Now that boreholes are being drilled below the North Sea off north-east England one may tentatively venture the prediction that they may show the Lias in this area to contain a higher proportion of sandy and ferruginous deposits than in Yorkshire.

DISTRIBUTION OF CAESIUM-137 IN THE HUMAN ORGANISM AND IN THE HUMAN FOETUS*

By A. KAUL, U. NAY, Prof. B. RAJEWSKY, Dr. W. STAHLHOFEN and F. UNNEWEHR
Max Planck-Institut fur Biophysik, Frankfurt am Main

FOR some years the distribution of the fission product caesium-137 within the human and animal organism has been studied by several investigators[1–5]. Much of this research has been aimed at finding the ratio of caesium-137 activity in soft tissue to that in bone. During the past few years, different ratios have been established by different groups of workers. Moreover, Yamagata *et al.*[3] and Anderson *et al.*[5] measured the content of caesium-137 in rib bones as a function of the age of the individual. The results obtained by these authors revealed that the specific activity of caesium-137 per g bone ash is at a minimum at the age of puberty. Oberhausen[6], however, published data on whole-body caesium-137 related to potassium indicating an increase of body caesium-137 from 6 years of age up to the age of puberty and showed that it was constant from that time on.

From results of whole-body counting of adult foetuses, McDonald *et al.*[7] suggest that there is a placental discrimination for caesium-137. This is surprising, since no placental discrimination is known for potassium.

Because of the different results published by several authors concerning the activity ratio of caesium-137 in soft tissue to that in bone, the caesium-137 activity as a function of age and the behaviour of the placenta for caesium, we measured the distribution of caesium-137 within the human and animal organism. We also determined the caesium-137 activity of samples of human bone and tissue for different age groups. In order to discover whether or not the placenta is a barrier for caesium we analysed foetal, placental and soft tissue of adults. The parameters to which the content of caesium-137 is related are fresh weight and content of potassium, since caesium is known to follow to a certain extent the metabolic pathway of its periodic relative potassium.

After chemical processing, the caesium-137 activity was measured by both a low-level beta-ray counting technique and by gamma-ray spectrometry. With the latter method the limit of detection was 5×10^{-11} c. caesium-137, but activities as low as 3 pc. could be detected by the anti-coincidence method[8].

The samples were wet-ashed in all cases, since caesium is reported to be volatile at temperatures higher than 450° C (ref. 9) and to be incorporated into the glaze of porcelain crucibles during dry-ashing[10]. The analytical recovery and the recovery of activity were 85 per cent in a pilot experiment using caesium-137 spiked apatite.

The preparates mounted for counting did not contain analytically determinable amounts of potassium. Therefore, no interference with the low beta-ray counting rate of caesium due to traces of potassium was to be expected. The content of potassium in tissue was determined by means of flame-spectrometry[11,12]. All analytical reagents used in these measurements were redistilled in a quartz apparatus prior to use.

From investigations performed by Hood and Comar[10] the distribution pattern of caesium-137 in the animal organism following a single administration is known. To examine the distribution pattern following continuous ingestion of fall-out caesium, we measured the specific caesium-137 activity in the stag. From these investigations the ratio of the activities of femoral bone-marrow : femoral compacta and muscular tissue adjoining the femur was shown to be 1 : 2, 9 : 26 (ref. 8). In reindeer a similar ratio was found for the activity in femoral bone marrow to the activity in muscles by Miettinen and Paakkola[13].

About 6 years ago, Yamagata[1–3] reported that human ribs and muscles contain the same level of caesium-137 activity. Some results indicated an even higher activity in human bones than in muscles. About 3 years later, the muscular activity of caesium was reported by Harrison *et al.*[4] to be 3–4 times the activity found in bones separated from their marrow. Our measurements revealed that the activity of caesium-137 in skeletal muscles is 15 times the content in marrow-free bones. The content in ribs was 2–3 times the activity in femora[8].

In our investigations we dealt chiefly with the rectus femoris, the addition of the sartorius and vastus medialis muscles occasionally. Femora were carefully cleaned from their bone-marrow and both parts were processed separately. The activity ratio between marrow and compacta was 1 : 1·2 (ref. 8).

As mentioned earlier, the specific activity of caesium-137 in ribs was found by Anderson and Gustavson[5] to decrease from birth to puberty and to rise again in the later years of life. The rising slope in later life was confirmed by Yamagata[1–3]. These results could not be confirmed by our measurements covering samples of soft tissue as well as femur and ribs taken from 5–10-month foetuses, still-borns and adults up to an age of 80 years. As may be seen from Fig. 1, the caesium-137 activity related to potassium in liver is 130 pc./gK and in brain 50 pc./gK in all stages of development. Since the standard deviation is at least 50 per cent due to the relatively small amount of foetal tissue being available, there is no significant difference between foetal and adult tissue. This is also true for the other organs being analysed.

In the upper graph of Fig. 2, the content in femoral tissue is shown to be 200 pc./gK, being also independent of age. In the lower graph of Fig. 2, the content of caesium-137 in bone is plotted against the non-mineral substance of bone (representing the amount of potassium in bone). With this correlation the specific activity of caesium-137 found in foetuses, children and adults are of the same order of magnitude. The factor of 2 is probably not significant owing to the relatively small number of foetuses analysed.

As to the question of placental transfer, the specific caesium-137 activity correlated to the content of potassium was assessed in the muscular tissue of adult women, in placental tissue and in foetal muscular tissue. The ratio between these three parameters as shown in Fig. 3 was unity within the biological variability.

It may be concluded from the results that: (1) The results of Yamagata[1–3] as well as those of Harrison *et al.*[4] showed the specific caesium-137 content of human muscular tissue to be 1–3 times that of bone tissue (Table 1). Our results, however, show that the specific caesium-137 content of muscular tissue is about 15 times that of compact bone. In the stag, the caesium-137 content in muscular tissue is also significantly higher than

Hood *et al.*	1 : 13	Rat	28 days after injection
Bretfeld	1 : 30		
Own values	1 : 9	Stag	Continuous uptake of fall-out ^{137}Cs with diet

Table 2. Specific Caesium-137 Content in Different Organs related to Muscular Tissue (=1·0)

Organ	Hood *et al.* (rat*)	Bretfeld (rat*)	Own values (man†)
Muscular tissue	1 0	1·0	1·0
Liver	0·22	0·32	0 65
Brain	0·29	0·21	0·25
Compacta	0 08	0·033	0 03

* 28 days after single injection.
† Continuous uptake of fall-out ^{137}Cs with diet.

that of bone tissue, though this ratio is somewhat lower than in man (Table 1). In cases of a single injection of caesium-137 into rats, results similar to ours for the distribution of caesium between muscular tissue and bone were published by Hood *et al.*[10] and recently by Bretfeld[14]. The results indicate a 13–30 times higher caesium-137 content in muscular tissue than that found in bone (Table 1). Besides this, the results show the activity ratio to be constant between the twentieth and seventieth days after injection. The conditions of a single injection may, however, be different from those of a continuous intake of caesium-137 in food. In order to find out whether or not both cases are comparable, we are undertaking animal experiments with continuous long-term feeding of caesium-137.

(2) For the distribution of caesium-137 between other organs such as liver and brain, our results indicate a specific caesium-137 content in brain of 25 per cent of that of muscular tissue and are in rather good agreement

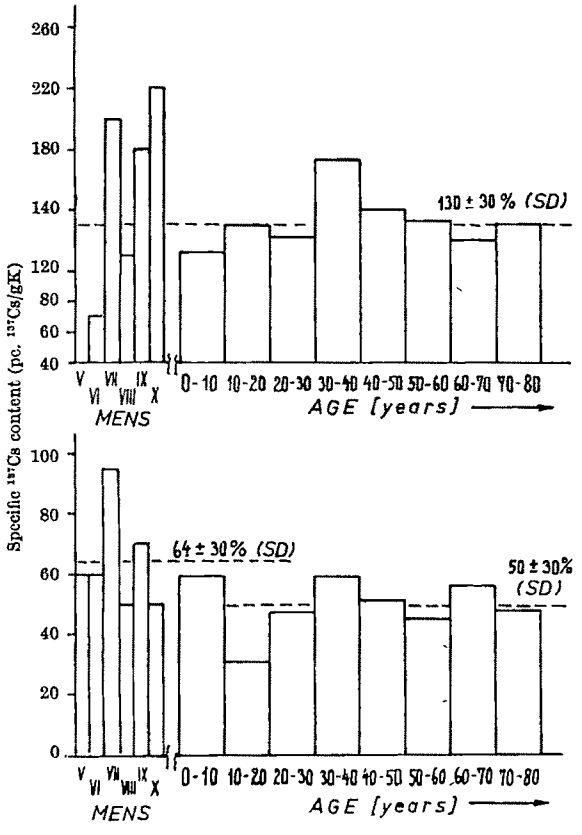

Fig. 1. Specific caesium-137 content of liver (top) and brain (bottom) as a function of the age of the individual

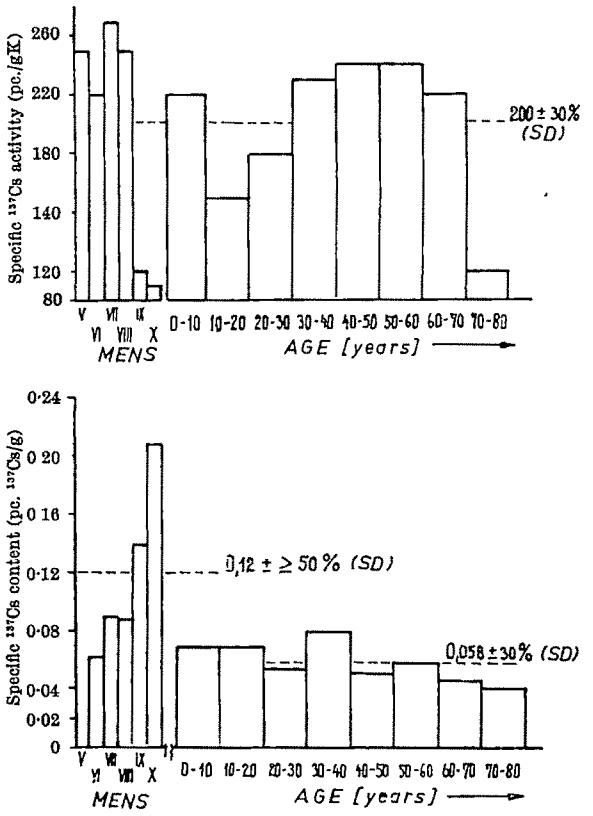

Fig. 2. Specific caesium-137 content of muscular tissue (top) and marrow-free bone (bottom) as function of age

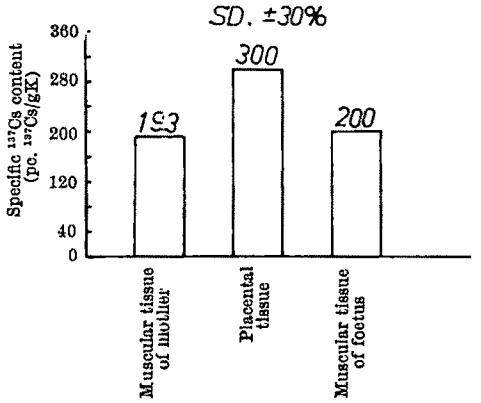

Fig. 3. Specific caesium-137 content of muscular tissue of mother and foetus and of placenta

with the results of animal experiments (Table 2). Though 2–3 times higher in man, the specific caesium-137 content in liver is also significantly lower than that in muscular tissue in man as well as in rat (Table 2).

(3) Contrary to results found by Anderson[5] and Yamagata *et al.*[1–3], no change with age in the specific caesium-137 content in different tissues including muscle and bone was observed in our cases.

From the fact that the specific activity of caesium-137 related to potassium in soft and bone tissues of adults is on the same level as the activities found in foetuses, it might be concluded that there is no significant placental discrimination for caesium-137 in the activity range under discussion. This conclusion is supported by the observation that the specific activity in muscular tissue taken from mother and foetus and the activity of the placenta proved to be on a comparable high level.

POLONIUM-210 ACTIVITY IN THE LUNGS OF CIGARETTE SMOKERS*

By Prof. B. RAJEWSKY and Dr. W. STAHLHOFEN
Max Planck-Institut fur Biophysik, Frankfurt am Main

In order to contribute further information on the natural radiation burden applied to the human body, we measured the ^{210}Po content in different parts of the lungs of human cigarette smokers and non-smokers. These investigations became necessary, since in 1964 Radford and Hunt[1] were able to demonstrate that a considerable portion of ^{210}Po, naturally occurring in tobacco, is inhaled with cigarette smoke. The average activity of ^{210}Po assessed in some brands of cigarettes in our laboratory is summarized in Table 1. The determination of ^{210}Po was performed in the following way. The tobacco samples were wet-ashed using nitric, hydrochloric and perchloric acids. Then ^{210}Po was enriched by a co-precipitation with Bi_2S_3 and subsequent separation by silver-plating[2]. The processed samples were counted in a methane flow counter. The background of α counts in the proportional counter is of the order of 2–3 counts per h. On average, 50 per cent of ^{210}Po present in one cigarette was detected in the main smoke stream, 15 per cent in the cigarette-ash and 35 per cent was measured in the butt. For filter cigarettes the maximum ^{210}Po activity detected in the filter was 5 per cent. It can thus be seen that a filter has no noticeable protective effect against polonium inhalation. These results are in good agreement with the measurements of Radford and Hunt[1] and the findings of Hill[3]. According to Radford and Hunt[1] the main smoke stream amounts to approximately 50 per cent of the total smoke. Based on this value and on our measurements, the ^{210}Po activity inhaled on average per cigarette is of the order of 0·1 pc. This means that, for an individual smoking 20 cigarettes a day, the daily ^{210}Po inhalation rate is 2 pc.

Table 1. Polonium-210 Content in Various Brands of Cigarettes

Tested brand of cigarette	^{210}Po content/g cigarette tobacco (10^{-13} c/g)	^{210}Po content/ cigarette (10^{-13} c./cig.)	^{210}Po content/ash of the cigarette (10^{-14} c./ash cig)	^{210}Po content/ butt (10^{-13} c./butt)	^{210}Po content/ total smoke (10^{-13} c./tot. ms.)
'Prince of Wales' (filter)	4·5	4·2	6 3	1 7 (0·17 in the filter tip)	1·9
'Rothandle' (Pfalz)	5·0	6·0	7·2	1·9	3·4
'*H B*' (filter)	4·1	4·1	5·3	1·7 (0·21 in the filter tip)	1·9
'Lucky Strike' (United States)	3 4	3·4	5·5	1·2	1 6
'Lucky Strike' (United States)	3·2	3·2	5·7	1·1	1·5

The inhalation rate, due to polonium occurring in the open air, was estimated by Jacobi[4] to be 0·02 pc. per day. This activity is only one-hundredth the value being inhaled by a moderate smoker. This is the reason why considerable differences are to be expected between the ^{210}Po activities to be measured in the lungs of smoking and non-smoking individuals.

The ^{210}Po activities found in different parts of the lung tissue of both smoking and non-smoking individuals are summarized in Table 2. For these analyses, the parenchymal tissue, the bifurcation and the bronchial tissue were dissected prior to measurement. The lung tissue dissected from heavy smokers was shown to contain three to four times the ^{210}Po activity found in the lungs of non-smokers.

In nine lungs of smokers, the ^{210}Po activity was also measured in the epithelium of the bifurcation, the secondary bifurcation and parts of the trachea, using a chemical procedure of wet ashing and subsequent chemical separation by silver plating[2]. The specific ^{210}Po activity of the epithelium was about ten times the value assessed in the remaining lung tissue. As the area of the epithelium is known from the section, the specific activities are also given per square unit. As can be seen from Table 2, the values range from 1 to 18 $\times$ 10^{-4} pc./cm^2.

The measured ^{210}Po activities in the epithelium are close to the limit of detection, due to the small amounts of sample material available. Long sample and background counting periods were therefore necessary. Here the average total error was $\pm$ 30 per cent, whereas in all the other cases of ^{210}Po counting in lung tissue, the error was only $\pm$ 15 per cent.

The measured specific ^{210}Po activities of the epithelium both per g wet weight and per square unit are smaller than the activities published by Radford and Hunt[1]. According to these authors, the activity in an upper part bronchial bifurcation, dissected from 73-year-old heavy smokers, is reported to be 0·03 pc. per square unit, a value which is, on average, 40 times higher than our own activities. Concerning the specific activity correlated with wet weight, our values are also on a lower level than the activities published by Radford *et al.*[5], who found activities up to 1·25 pc. per g wet tissue in the epithelium of the segmental bifurcation dissected from smokers.

* Paper presented at the Eleventh International Congress of Radiology, Rome, September 1965.

Our activities per square unit measured in the epithelium of the bifurcation, the secondary bifurcation and in the lower part of the trachea are in good agreement with Jacobi's theoretical calculation of the ^{210}Po activity in the epithelial tissue, making allowance for the ciliary movement and for transfer of ^{210}Po from the alveolar zone into the bronchial tree[4]. The bronchial content for the segmental and terminal region is reported by him to be of the order of magnitude of 10^{-4} pc. per square unit. This calculation is based on the assumption that the rate of inhalation would be 2 pc. ^{210}Po per day, that the biological half-life of this nuclide in the lung would be 5 days, and that its deposition rate within the total respiratory tract would be 80 per cent with half this value deposited in the alveolar zone. According to Jacobi, the specific ^{210}Po activity in alveolar tissue is 6×10^{-15} c. per g wet tissue, and this activity is in good agreement with our findings for the specific ^{210}Po activity, measured in the parenchymal tissue.

Hill investigated the distribution of α-ray tracks in vacuum-dried epithelium samples dissected from the bronchial bifurcation of smokers. These measurements were performed using the stripping film method and showed no noticeable differences in the enrichment of α-ray tracks[5]. This means that the distribution pattern of ^{210}Po in bifurcation places shows no evidence of inhomogeneities. In other words, there is an equal distribution of ^{210}Po in the epithelium. His values were of the same order of magnitude as the theoretical values given by Jacobi, that is, 10^{-4} pc./cm^2 (ref. 6).

Jacobi[4] also calculated the burden applied to the human respiratory tract by naturally occurring radiation. He made special allowances for the dose absorbed in the range of the layer of so-called basal cells because this layer of the bronchial epithelium is especially important in carcinogenesis. For this calculation, the α-ray activity was assumed to be distributed homogeneously in the middle layer of the mucous layer situated over the bronchial epithelium. The calculation of the distribution pattern of the depth dose in the bronchial epithelium was based on the α-ray absorption within the mucous layer and on the stopping power of tissue as a function of α-ray energy.

According to Miller[7] and Altshuler[8], the thickness of the upper mucous layer is 10μ in the zone of the trachea and somewhat less in the region of the terminal bronchi. The average distance of the layer of basal cells from the mucous layer is 60–90μ within the trachea and 20–40μ in the region of the terminal bronchi. The distribution pattern of the α-depth dose emitted from ^{210}Po demonstrates that α-rays do not reach the critical layer of basal cells within the trachea, the main bronchia or the lobate bronchia, and therefore do not affect this layer at all. The critical regions for ^{210}Po are the terminal-, the subsegmental- and the segmental-bronchia.

On this basis, we calculated the α-ray dose absorbed in the critical zones using the activities determined in our laboratory. For this, the area activity of ^{210}Po determined in the bifurcation zone was assumed to be identical to the activities in the region of segmental or terminal bronchi, and the ^{210}Po activity was presumed to lie in the mucous layer. The calculated values are summarized in Table 3. The average dose-rate for the basal cell layer is 41 mrem per year or 1·0 rem over 25 years, respectively, in the subsegmental bronchi; and approximately 79 mrem per year, or 2·0 rem over 25 years, respectively, in the terminal bronchia. These values are small compared with the dose-rate given by Radford and Hunt, which is 165 rem over 25 years at the minimum.

Table 3. ALPHA DOSE-RATE IN BRONCHIAL EPITHELIUM

Object	Average activity (pc./cm^2)	Dose-rate (mrem/a) $QF = 10$
Basal cells of subsegmental bronchi	8×10^{-4}	41 (average) 86 (maximum)
Basal cells of terminal bronchi	8×10^{-4}	79 (average) 150 (maximum)

The ^{210}Po dose-rate based on our measurements for bronchial epithelium is small compared with a dose-rate in the range of 1–2 rem per year originating from the decay of naturally occurring radon and thoron and their short-lived daughter-products. This dose-rate was calculated by Jacobi in the basal cell layer of segmental and subsegmental bronchi[4]. This would seem to show that carcinogenesis caused by inhalation of ^{210}Po with the tobacco smoke is rather unlikely.

We thank Dr. Unnewehr, Dr. Rossenbeck and Dr. Dauber for their valuable help in dissecting pathological material. This work was supported by the Bundesministerium des Innern, Federal Republic of Germany.

RADIOSENSITIVITY OF IMMUNOLOGICALLY ACTIVATED CELLS

By DR. M. C. BERENBAUM
Surgical Unit, St. Mary's Hospital Medical School, London

NUMEROUS investigations have shown what appear to be clear-cut differences in the radiosensitivity of the immune response before and after exposure to antigen. Whole-body irradiation strongly inhibits the response if it is administered before the antigen and is relatively ineffective if given afterwards[1,2]. Radiosensitivity may fall sharply within a few hours of giving the antigen[1] or more slowly over some days[2]. With few exceptions[3] the production phase of the response has been found to be radio-resistant. These marked changes in the radiosensitivity of the response have led to the assumption that the cells mediating the response also change in radiosensitivity, but this does not necessarily follow.

Consider a model (Fig. 1) in which, before exposure to antigen, a few cells produce antibody at levels below the threshold of detection, the number of such cells being kept constant by a balance of a low mitotic frequency with a relatively long life. On antigenic stimulation, the cells increase rapidly, raising the level of serum antibody above the threshold of detection (Fig. 1*A*). Let the radiosensitivity of the cells remain constant so that a given dose of radiation destroys or inactivates the same fraction of cells whenever it is given in relation to the time of giving the antigen. Let the half-life of such irradiated, antibody-producing cells be short compared with the half-life of serum antibody.

If irradiation occurs before administration of antigen, the surviving cells may be envisaged as multiplying relatively slowly to restore the original number. Irradiation long before immunization allows time for complete restoration and the immune response will be normal (Fig. 1*B*). The shorter the interval between irradiation and immunization the less recovery will have occurred (Fig. 1*C*). In this simple model let the responses in such

cases differ from the normal only in the number of cells taking part, so that the curves describing the rise and fall in cell numbers and antibody levels will be normal in shape but displaced downwards (Fig. 1*C*). This results in a lower peak antibody titre and, because of the threshold below which antibody is not detectable, in apparent prolongation of the induction period and slowing of the rate at which antibody rises once it has passed the threshold.

When irradiation occurs late in the production phase serum antibody has already reached a high level (Fig. 1*F*). The number of antibody-forming cells falls rapidly after irradiation, the survivors continuing to rise and fall at the rates prevailing normally. If the surviving fraction is small, the rate of antibody production is at first negligible. The level of serum antibody therefore falls with approximately its characteristic half-life until production by surviving cells or their progeny becomes appreciable. The effects of irradiation after administration of antigen may therefore be partly masked by the relatively slow fall in the level of antibody already present in the serum. At least up to the time when peak titres are reached, the greater the interval between immunization and irradiation, the greater the contribution of already-formed antibody to subsequent levels (Fig. 1*D–F*).

The lower part of Fig. 1 shows the effects on peak titre, length of induction phase and rate of increase of antibody above the threshold when radiation is given at different times before or after the antigen in this model. These have been derived by inspection from the curves in the upper part of Fig. 1. It is seen that all these parameters, which are commonly used as indices of the radiosensitivity of the immune response, would change markedly during the response, even if there were no change at all in the radiosensitivity of the cells concerned.

For simplicity this model ignores effects on precursor cells not forming antibody and any radiation effects other than cell destruction. Moreover, it takes no account of possible homoeostatic mechanisms governing the number of cells producing antibody that might tend to counteract the immunosuppressive effects of radiation. A model so oversimplified cannot be expected to account quantitatively for experimental findings and there are important

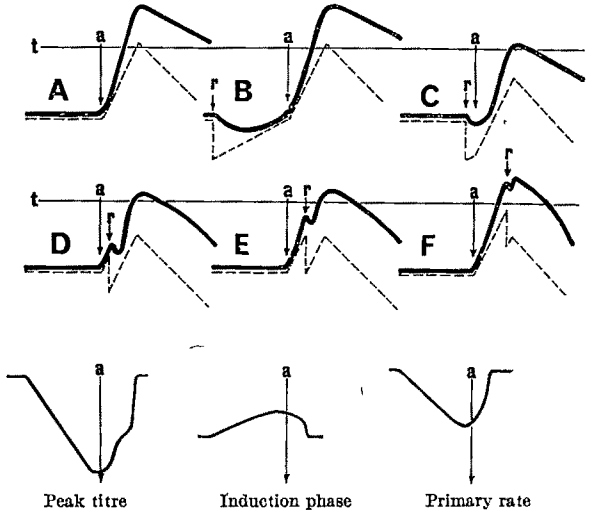

Fig. 1. Model of an immune response with constant cellular radiosensitivity. – – – – –, Log No. of antibody-forming cells; ————, serum antibody titre; *a* ↓, injection of antigen; *r* ↓, irradiation; *t*, threshold for detection of serum antibody. *A*, Normal response; *B—F*, responses with irradiation at different times in relation to administration of antigen (note that the fall in the log No. of cells is the same throughout). In the lower part of the Figure the horizontal axis (on the same scale as that in the upper part) shows the time of irradiation before or after administration of antigen, indicated by *a* ↓. The vertical axes show, respectively, peak titre, length of induction phase and the primary rate of increase in antibody above the threshold. These curves, therefore, which have been drawn through points derived by inspection from the curves in *A—F*, show what effect irradiation at different times would have on these parameters of the immune response in this model

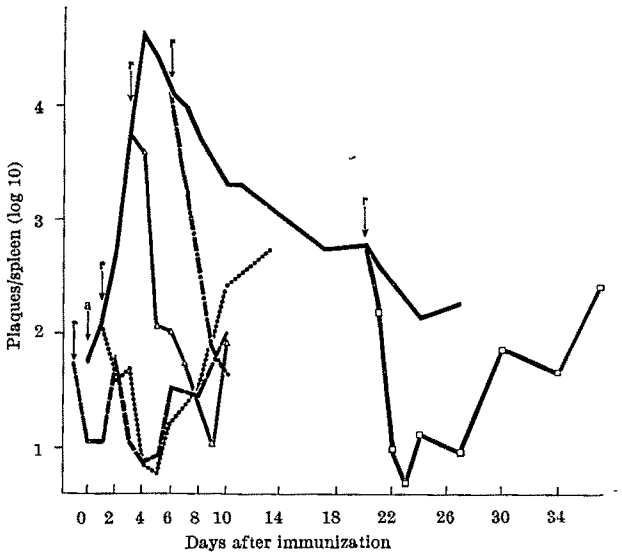

Fig. 2. Effect on numbers of haemolysin-forming cells of irradiation with 450 r. on days −1, +1, +3, +6 or +20. *a* ↓, injection of antigen; *r* ↓, irradiation; ————, controls, – – – – –, day −1 group, · · · · · ·, day +1 group; ——△——△——, day +3 group, ——·——·——, day +6 group; ——□——□——, day +20 group. Curves drawn through geometric means of each group, 5—10 mice per day per group

qualitative findings not accounted for; for example, the adjuvant effect of radiation in some circumstances. However, the overall similarity of the curves generated by the model to those found experimentally[1,2] suggested that it would be worth investigating directly the radiosensitivity of antibody-forming cells at different stages of the immune response. The following experiments were therefore performed.

Male *A2G* mice were injected intraperitoneally with 0·2 ml. of a 10 per cent suspension of formolized sheep red cells in saline. Groups of mice were killed at intervals and the numbers of haemolysin-forming cells in their spleens counted by Jerne's method[4]. Mice were irradiated either one day before giving the antigen or 1, 3, 6 or 20 days afterwards with 450 r. (65–75 r./min, 220 kVp, 15 m.amp, 0·5 mm copper and 1 mm aluminium added filtration, target distance 34·5 cm). The results are shown in Fig. 2. It appears that this dose of radiation causes a rapid fall in the number of antibody-forming cells whenever it is given. There is no evidence of an increase in radio-resistance after the antigen has been given, even late in the production phase of the response.

In view of the possibility that cells producing 19*S* haemolytic antibody might be atypical in radiosensitivity, further experiments were performed in which the numbers of cells forming haemagglutinin were counted. A modification of Zaalberg's method[5] was used; 1-ml. portions of spleen cell suspensions and 0·25 per cent sheep red cell suspensions in cold tissue culture medium '199' were mixed and stood overnight in the refrigerator in 13 × 150 mm 'Pyrex' test-tubes. These were then rotated at 28 r.p.m. for 10 min at room temperature in a plane 33° from the horizontal and the number of agglutinates counted in a Fuchs–Rosenthal chamber. The results are shown in Fig. 3. Again, radiation causes a rapid fall in the number of antibody-producing cells and there is no evidence that radio-resistance rises after the antigen is given.

There are two notable differences between the curves obtained here and those predicted by the model. First, irradiation a day before giving the antigen causes a smaller fall in cell numbers than irradiation after the antigen has been given. This finding is unexpected and difficult to explain. Secondly, cell numbers tend to rise toward control levels after the initial post-irradiation fall. This suggests the operation of homoeostatic mechanisms.

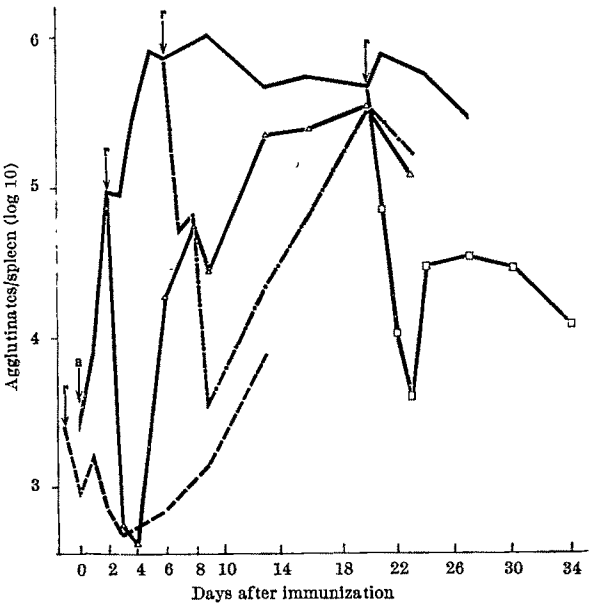

Fig. 3. Effect on numbers of agglutinin-forming cells of irradiation with 450 r. on days −1, +2, +6 or +20. *a* ↓, injection of antigen; *r* ↓, irradiation, ————, controls; – – – – –, day −1 group, ——△——△——, day +2 group; ——·——·——·——, day +6 group; ——□——□——, day +20 group Curves are drawn through the geometric means of each group, 5 mice per day per group

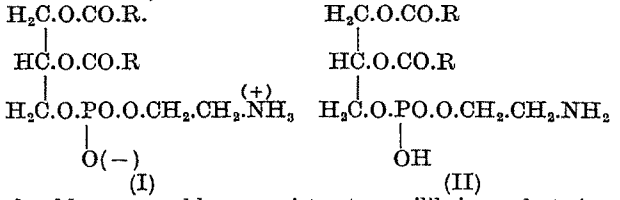
It is not possible to determine the surviving fraction of cells from simple inspection of the curves because part of the fall in cell numbers may have been due to damage to precursor cells which, in any event, were not forming antibody and were therefore not counted. However, if the proportion of cells functioning at the lowest point of the post-irradiation fall is assumed to be the surviving fraction, most of the curves obtained here would suggest that the fraction surviving a dose of 450 r. is about 0·5–1 per cent.

Now, when immunologically competent cells are irradiated before antigenic stimulation, the fraction surviving a dose of 450 r. is estimated variously as 0·4 per cent[6], 0·04–1 per cent[7], 0·6 per cent[8] and 0·3 per cent[9]. There does not, therefore, appear to be good evidence of a material change during the immune response in the radiosensitivity of the cells that mediate the response.

These results do not exclude the possibility that cell radiosensitivity may change to some extent at different stages of the response, especially at stages not examined in these experiments. They suggest, however, that the marked fluctuations in radiosensitivity found when certain end-results of the immune process are investigated may, to some degree, be experimental artefacts due to the delay with which changes in cell population are reflected in serum antibody levels and to the impossibility of following changes in serum antibody below the threshold of detection.

Many agents differ from radiation in the timing of their immunological effects, being relatively ineffective if given before the antigen and most effective if given some 1–4 days afterwards[10]. If the interpretation given here is correct it follows that cellular sensitivity to such agents cannot remain constant throughout the response but must change markedly. This possibility is under investigation.



I thank the Medical Research Council and British Empire Cancer Campaign for Research for financial support, Dr. E. A. Wright for irradiation facilities and Miss D. Lyall for help.

EVIDENCE FOR THE INVOLVEMENT OF IONIZATION IN THE POLYMORPHISM OF A PHOSPHOLIPID

By Dr. J. J. WREN and DANUTA S. MERRYFIELD
The Lyons Laboratories, London

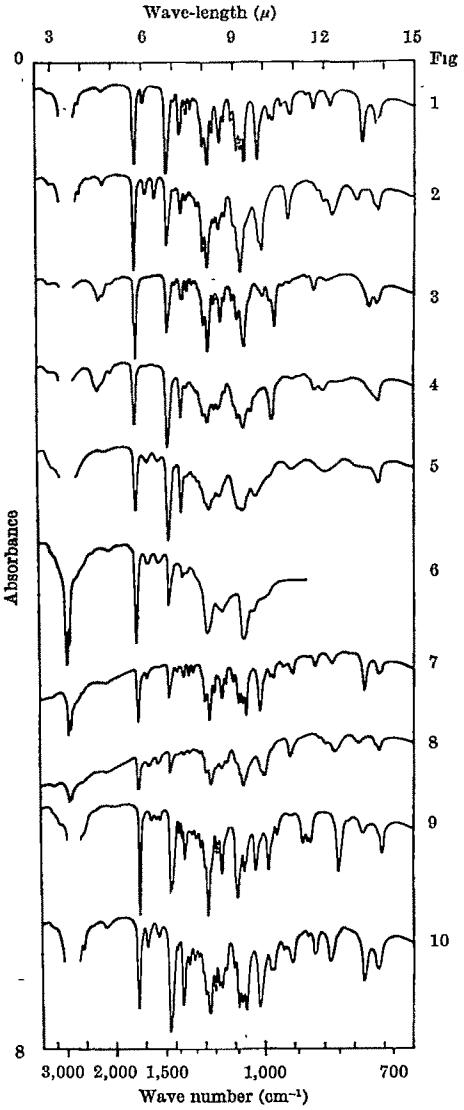
WHETHER a neutral α-phosphatidylethanolamine molecule exists as the zwitter-ion (I) or as the un-ionized tautomer (II) has been of interest for some time[1]. In a solution, both tautomers:

should presumably co-exist at equilibrium, but in a crystal, only one tautomer might be expected. However, although numerous infra-red spectra of solid α-phosphatidylethanolamines have been published, which have been interpreted to indicate the existence of at least three polymorphs[2], none gives a clear indication of tautomeric state. We have now prepared DL-α-(dipalmitoyl)-phosphatidylethanolamine in a crystalline form which, from infra-red spectroscopic evidence, appears to consist of the un-ionized tautomer (II). Other polymorphs appear to contain the zwitter-ionic tautomer (I), perhaps in combination with the un-ionized.

van Veen and Verkade[3] were the first to point out that discrepancies between spectra of α-phosphatidylethanolamines could be attributed to polymorphism. They published the infra-red spectra of two forms of the dipalmitoyl compound, which they termed *A* and *B* polymorphs. Later, Chapman and co-workers[2,4,5] agreed with the findings of van Veen and Verkade, but reported also a *C* polymorph which is formed at temperatures above the melting-point of the hydrocarbon chains; this means that the *C* polymorph is liquid-crystalline.

Starting with commercial preparations of DL-α-(dipalmitoyl)phosphatidylethanolamine, we have crystallized various specimens of which the spectra agree well with all three published types. However, we also obtained many spectra similar to the '*B*-spectrum'[3] but in which certain absorptions—most notably a peak near 1,550 cm^{-1}—were weakened. Gas chromatography showed that the spectral differences were not due to differences in fatty

acid composition, which was approximately 90 per cent palmitate in all samples. However, on thin-layer chromatograms of silica gel G developed[6] with chloroform–methanol–acetic acid–water (65 : 15 : 10 : 4, by volume) all the specimens gave two major zones in the region where α-phosphatidylethanolamine was expected to be. (There were also minor zones of higher and lower R_F which were apparently formed by palmitic acid and lysophosphatidylethanolamine respectively.) Attempts to distinguish between these zones with numerous spray reagents failed. But infra-red analysis of materials obtained by preparative layer chromatography showed that the slower zone (R_F 0·67) was formed by α-phosphatidylethanolamine, whereas the faster (R_F 0·78) was formed by the β-isomer. The identity of β-(dipalmitoyl)phosphatidylethanolamine was confirmed by comparing its chromatographic behaviour and infra-red spectrum (Fig. 9) with those of an authentic specimen obtained from the late Dr. Malkin's collection[7]. (Specimens were obtained from this collection through the courtesy of Prof. Wilson Baker.) Some other workers have also observed two major zones on thin-layer chromatograms of commercial α-phosphatidylethanolamine preparations[8,9]. Our evidence indicates that some preparations, claimed to consist of either the DL-α- or the L-α-isomer, contain up to 30 per cent of the 'unnatural' β-isomer, which is very disturbing in view of the widespread use of these preparations for biochemical and biophysical studies.



When the commercial preparations were subjected to column chromatography on silicic acid, using 12 per cent methanol in chloroform as eluent[10], they gave partly resolved peaks of (in order) the β- and α-isomers, and late fractions contained the α-isomer in a high state of purity. As the fractions were stored at −20° C and the solvent slowly evaporated, crystals were formed which gave the infra-red spectrum shown in Fig. 1. This contains no peak at all near 1,550 cm^{-1}. An alternative and more rapid method for obtaining crystals with the same spectrum was to prepare a near-saturated solution in boiling chloroform, add a trace of ammonium hydroxide, cool to −20° C with shaking, and desiccate the crystals that separated over phosphorus pentoxide. Crystallization from chloroform or ethanol by more conventional methods usually caused the appearance of a small peak near 1,550 cm^{-1}, the spectra resembling Fig. 10. However, cooling a highly concentrated, boiling solution in ethanol gave crystals with the spectrum shown in Fig. 2. This spectrum was also observed after crystals with the other spectra (Figs. 1 and 10) had been briefly heated to 140° C and cooled to room temperature.

It appears that the spectra published by van Veen and Verkade[3] represent impure polymorphs. Following their nomenclature, we attribute Fig. 2 to polymorph *A* and Fig. 1 to polymorph *B*. Hence, van Veen and Verkade's '*A*-spectrum' represents polymorph *A* contaminated with *B* and their '*B*-spectrum' represents polymorph *B* contaminated with *A*. Whereas Chapman and Collin[6] reported that DL-α-(dimyristoyl)phosphatidylethanolamine was relatively stable in the *C* polymorphic form at room temperature, this was not true of our purified dipalmitoyl compound. At 140° C a microcrystalline film of our compound gave a spectrum characteristic[2] of the *C* polymorph, but after being left for only 1 h to cool to room temperature it gave the spectrum of the *A* polymorph (Fig. 8). We were only able to obtain crystals of the *C* polymorph with some stability at room temperature by slowly evaporating a solution in pure dioxan (see Fig. 5).

Storage for a week at −196° C, or for 30 min at other temperatures up to 126° C, did not change the spectrum (taken at room temperature) of either the *A* or the *B* polymorph. These findings appear to conflict with those of Chapman[2].

When some of the β-isomer was deliberately added to the α- it again became impossible to crystallize the *B* polymorph in pure state, and when an equal quantity was added it was only possible to obtain crystals with the spectrum of the *A* polymorph. This may partly explain why all previously published[2–4,11–16] spectra of crystalline, saturated α-phosphatidylethanolamines appear to represent mixtures of polymorphs. Other possible explanations include the presence of different impurities, the use of other crystallization techniques, and the use[2,4,12,13,16] of the potassium bromide disk technique for infra-red spectroscopy: this is notorious[4,17,18] for producing artefacts. However, our evidence does not preclude the possibility that true polymorphs other than *A*, *B* and *C* may exist, nor that these could be hybrids of *A* and *B*. (That the *A* and *B* polymorphs have similar stability might favour the existence of hybrids.)

The *A* and *B* polymorphs gave satisfactory analyses for carbon, hydrogen, nitrogen and phosphorus, were readily interconvertible by the methods described, and gave the same spectrum (Fig. 6) after dissolving in tetrachloroethylene. Spectra taken on Nujol mulls (Figs. 1 and 2) were indistinguishable from those taken on microcrystalline films (Figs. 7 and 8).

Figs. 1–10. 1, *B* Polymorph of DL-α-(dipalmitoyl)phosphatidylethanolamine, as Nujol mull. 2, *A* Polymorph (Nujol). 3, Deuterated *B* Polymorph (Nujol). 4, Deuterated *A* Polymorph (Nujol). 5, *C* Polymorph (Nujol). 6, Solution of *A* or *B* Polymorph (or of β-(dipalmitoyl)phosphatidylethanolamine) in tetrachloroethylene. 7, *B* Polymorph, as microcrystalline film. 8, *A* Polymorph, as microcrystalline film. 9, β-(Dipalmitoyl)phosphatidylethanolamine (Nujol). 10, *B* Polymorph of DL-α-(dipalmitoyl)phosphatidylethanolamine (compare with van Veen and Verkade (ref. 3)) contaminated with *A* Polymorph (Nujol)

Crystallization from pure chloroform in the presence of deuterium oxide, or exposure of the *B* polymorph to deuterium oxide vapour for 10 days, produced deuterated *B* polymorph (see Fig. 3); when this was exposed to water vapour the spectrum shown in Fig. 1 was restored. The *A* polymorph underwent deuterium- or hydrogen-exchange roughly ten times more slowly than the *B*, and tended to yield deuterated *B* polymorph as well as deuterated *A*. (Another physical difference observed was that the *A* dissolved in chloroform more rapidly than the *B*.) Deuterated *A* polymorph (see Fig. 4) was best obtained by heating deuterated *B* polymorph.

The spectra depicted in Figs. 1 and 2 show substantial differences which cannot be ascribed merely to differences in the packing of hydrocarbon chains. Moreover, many absorptions that are not common to both spectra are shifted by deuteration, thus clearly implicating the polar parts of the molecules.

The $NH_3^{(+)}$ group gives rise to at least two peaks, attributed to deformation modes[19–21], in the region 1,485–1,660 cm^{-1}. For example, the spectra of glycine polymorphs[22], α-phosphatidylserines[23], and α-phosphatidylethenolamine solutions (see Fig. 6)[24], all show such peaks, one occurring fairly near 1,640 cm^{-1} and another near 1,550 cm^{-1}. The NH_2 group normally gives rise to only one peak in this region, usually[19–21] above 1,600 cm^{-1}, so that a peak near 1,550 cm^{-1} in the spectrum of a pure α-phosphatidylethanolamine should indicate $NH_3^{(+)}$ groups specifically. This conclusion is supported by Baer and Blackwell's finding[24] that *N*-methylated α-phosphatidylethanolamine derivatives give no such peak.

The absence of any peak near 1,550 cm^{-1} in Fig. 1 is evidence that our *B* polymorph contains no $NH_3^{(+)}$ groups, and, hence, that it consists of the un-ionized tautomer (II). Broad-based absorption in the N—H stretching region and peaks at 1,645, 810 and 746 cm^{-1}, all sensitive to deuteration, are consistent with the presence of NH_2 groups[19,20]; and peaks at 2,550 and 1,015 cm^{-1} can be attributed respectively to the stretching[14] and deformation[23,25] vibrations of POH groups. In the spectrum (Fig. 3) of the deuterated *B* polymorph, the appearance of a peak at 2,195 cm^{-1} and a shoulder at 1,275 cm^{-1} can be attributed to ND_2 stretching[19] and deformation[26,27] vibrations, respectively, and a shoulder at 2,000 cm^{-1} and a peak at 735 cm^{-1} to POD vibrations[19]; enhancement of the peak at 965 cm^{-1} may result[26,27] from the shifting of a C—N stretching vibration from near 1,015 cm^{-1}. Since deuteration changes the pattern of peaks near 1,080 cm^{-1} attributable[28] to POC groups it appears that these are hydrogen-bonded. However, deuteration does not perceptibly change the peak at 1,730 cm^{-1} and shoulder at 1,745 cm^{-1} attributed to C=O stretching vibrations. The peak is at anomalously low frequency for phospholipids and if, as it seems, this is not due to hydrogen bonding, it may be due to nucleophilic interaction between amino and carbonyl groups, visualized $H_2N : \underset{\downarrow}{\overset{\downarrow}{C}}=O$.

Analogous interpretations of the spectra of the *A* polymorph (Fig. 1) and its deuteration product (Fig. 4) indicate the zwitter-ionic tautomer (I). However, several features of these spectra (such as peaks attributable to POH and POD stretching) suggest that the un-ionized tautomer may also be present, perhaps in equal quantity. Since the shapes of the peaks near 720 cm^{-1}, assigned to CH_2 rocking vibrations, are different in Figs. 1 and 2 (also in Figs. 7 and 8, which were obtained without Nujol), we conclude that the hydrocarbon chains are packed differently in the *A* and *B* polymorphs. This accords with some results obtained by X-ray diffraction[2,28]. (It appears that the designation *A* was applied to the same polymorph independently by workers using X-ray[26] and infra-red[3] methods.)

The spectrum of the liquid-crystalline *C* polymorph (Fig. 5) shows less fine structure than those of the *A* and *B* polymorphs but, as expected, more than that of the solution (Fig. 6). Peaks near 1,550 cm^{-1} indicate that the *C* polymorph and the solution contain at least some zwitter-ionic tautomer.

Since the crystalline state of phospholipids in biological membranes is thought to be of vital significance[2,29] the question may be raised whether its involvement with ionization could facilitate ion transport.

INHIBITION OF DNA SYNTHESIS BY ULTRA-VIOLET LIGHT UNDER CONTROLLED TEMPERATURE

By Dr. J. E. CLEAVER

The Massachusetts General Hospital, Boston

THE dose response curve for the inhibition of DNA synthesis by ionizing radiations[1–7] or by ultra-violet light[8,9] has in most cases been claimed to be a complex multiphasic curve. In the case of the *in vitro* experiments this curve has been interpreted in terms of two components; one component, the S_1, predominates at the lower doses, and the other, the S_2, predominates at the higher doses[4]. In many cases, however, irradiations have been performed at room temperature (20°–25° C), and the subsequent incubations with labelled precursors of DNA performed at the normal incubator temperature of 37° C. In other cases the precise temperature conditions have not been stated (Table 1). In the experiments for which the temperatures have not been stated, it is probable that the irradiations would have been performed at room temperature and the subsequent incubations at

37° C. This is because it is unlikely that the effort would be made to perform irradiations at 37° C and this procedure then left unmentioned. In two cases[10,11], however, care was taken to ensure a uniform temperature of 37° C throughout the irradiation and labelling procedures, and the resulting dose-response curve was not multiphasic but followed a simple one-hit curve. These results of Smith[10] and of Manasek *et al.*[11] make it possible to explain the multiphasic curve which has been obtained using ionizing radiations as an artefact arising from the temperature changes during the experiments. On account of this possibility it is necessary to determine the dose response curve for the inhibition of DNA synthesis by ultra-violet light under controlled temperature conditions. The result of this determination is described in the following paragraphs.

Cultures of both mouse *L* strain and human amnion, *FL*, strain were used in these experiments. *L* strain was grown in Eagle's basal medium supplemented with 10 per cent bovine serum and the *FL* strain in nutrient mixture *F*10 supplemented with 20 per cent calf serum (all growth media and sera were obtained from Grand Island Biological Co.). Eagle's medium is thymidine-free but *F*10 contains thymidine at 3×10^{-6} moles/l. In order to prepare ^{3}H-thymidine (^{3}HTdr) solutions of known specific activity, ^{3}HTdr was added to Eagle's medium or to specially prepared Tdr-free *F*10. Monolayer cultures were grown on quartz coverslips which formed one window of small culture chambers similar to those described first by Perry *et al.*[12]. Cultures in the exponential phase of growth were irradiated through the quartz coverslip without disturbing their normal environment of growth medium which was at the optimum *p*H, and fully oxygenated. The ultra-violet light source was a 15-W General Electric germicidal lamp, and a constant flux of approximately 20 ergs/mm^2/sec at 2537 Å was used throughout the experiments. All the irradiations and all the subsequent incubations in ^{3}HTdr were performed in a warm room at

Where the D_{37} values are not stated in the original papers, approximate estimates have been made from the published diagrams. In the case of ultra-violet light the approximate D_{37} values are incident flux, not absorbed dose.

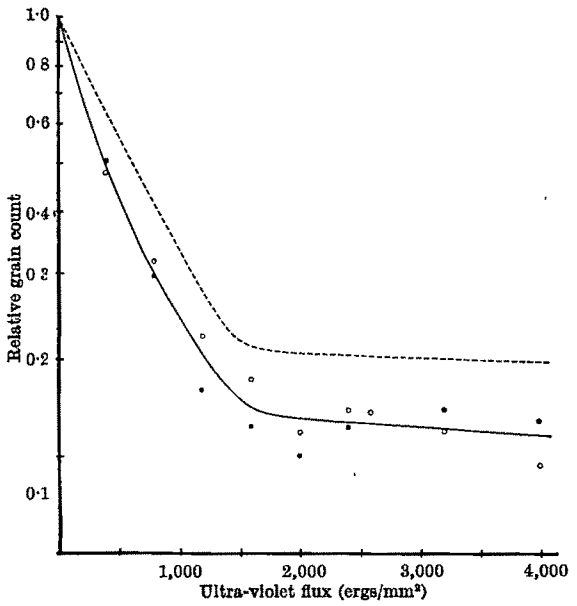

Fig. 1. Incorporation rates of ^{3}HTdr into DNA after exposure to ultra-violet light. ○, *FL* strain, 1·25 μc./ml., 3 c./mmole, ^{3}HTdr; ●, *L* strain, 2·5 μc./ml., 3 c./mmole, ^{3}HTdr. Each point represents the mean of duplicate experiments. The dotted line represents the dose-response curve obtained using *L* strain cells, in which irradiation was at room temperature, 20° C, and labelling at 37° C. This curve has been taken from a previous publication (ref. 9) in which a different dose rate (47 ergs/mm^2) and different ^{3}HTdr concentration (5 μc./ml., 2 c./mmole) were used to those used in the experiments described here

37° C. Controls were maintained on every quartz coverslip by shielding a region completely from the incident light. Immediately after the irradiations the culture chambers were opened and the medium replaced with culture medium containing ^{3}HTdr (Schwartz Bioresearch). The ^{3}HTdr was used at 2·5 μc./ml., 3 c./mmole (Fig. 1), 2·5 μc./ml., 0·36 c./mmole (Table 2) for the *L* strain, and at 1·25 μc./ml., 3 c./mmole for the *FL* strain. After allowing the cultures to continue growth for 10 min in labelled medium they were rinsed in Earle's balanced salt solution and fixed in acetic acid–alcohol (1 : 3) and then air dried. All the cultures were treated with 2 per cent perchloric acid at 4° C for two periods of 1 h to ensure complete removal of the acid-soluble pool. It was assumed that the ^{3}H-labelled material which was not removed by this fixation and acid hydrolysis had been incorporated into DNA[13,14]. Autoradiographs were then prepared using Kodak '*NTB*3' liquid emulsion and after exposure at 4° C for periods of 2–26 days these were developed with Kodak '*D*19', fixed, washed and afterwards stained through the emulsion with Ehrlich's haematoxylin. Grain counts were made over fifty labelled cells in both the irradiated and control regions of each culture, cells being regarded as unlabelled if there were five grains or less over the nucleus. The average grain count/labelled cell was taken as a measure of the amount of 3HTdr which had been incorporated into DNA during the labelling period in that region of the culture. For short labelling times of the order of 10 min, the average grain count can then be taken as a measure of the average rate of DNA synthesis at the time of labelling[15]. Cultures labelled under identical conditions, but with the autoradiographs exposed for different periods of time, gave control grain counts/labelled cell/day exposure which were distributed with a standard error of 10 per cent. A similar standard error has also been obtained in earlier experiments using Kodak '*AR*10' emulsion[16].

Table 2. Ratios of Average Grain Counts in Irradiated to Control Cultures as a Function of Incubation Time in ^{3}HTdr

(2·5 μc./ml., 0·36 c./mmole for *L* strain; 1·25 μc./ml., 3 c./mmole for *FL* strain) (expressed as a percentage)

Incubation time	30 min	1 h	2 h	3 h	4 h
L strain (400 ergs/mm^2)	45	29	22	21	20
FL strain (400 ergs/mm^2)	37	27	14	10	8

A series of cultures were irradiated with a total flux of ultra-violet light that ranged between 400 and 4,000 ergs/mm², labelled with ^{3}HTdr for 10 min and fixed. Grain counts on autoradiographs of these cultures were determined in the manner already described. The results are shown in Fig. 1, and it can be seen that the responses of the two cell types, which have been determined under almost identical conditions, can be represented by the same dose-response curve. (The difference between the concentrations of ^{3}HTdr solutions used for labelling the two cell types is insufficient to make differences in pool sizes a significant factor in these results[17,18].) It was found by Jasinska and Michalowski[19] that the inhibition of DNA synthesis in rat bone marrow cells and in ascites cells by X-rays could also be represented on a single dose-response curve, when both cell types were used under the same conditions. It is consequently possible that the differences in the D_{37} values (Table 1) which have been obtained by different workers is due to differences in experimental techniques rather than differences between cell types. One factor which is particularly important in this respect is the duration of the labelling period after irradiation, as the following discussion will indicate.

The incorporation of ^{3}HTdr into tissue culture cells in the exponential phase of growth proceeds at a constant rate for several hours and this results in a linear increase in the average grain count in autoradiographs as a function of the incubation time[16]. After irradiation with ultra-violet light the rate of DNA synthesis is not constant, but varies in a manner which depends both on the total flux and the time elapsed after irradiation[6]. This results in a non-linear increase in the average grain count in irradiated cultures as a function of the incubation time. Consequently, the ratio of the average grain counts in the irradiated to the control cultures, which can be used as a measure of the irradiation effect, will depend on both the total flux of ultra-violet light and the time for which the cultures are incubated in ^{3}HTdr between irradiation and fixation. In Table 2, this dependence is illustrated for the case of increasing incubation time in ^{3}HTdr, for both the cell types, after a single exposure to ultra-violet light.

It can be seen from Table 2 that the longer the incubation time in ^{3}HTdr after irradiation, the greater is the relative reduction in average grain counts and the higher the apparent sensitivity. This is probably a major reason for the lower D_{37} values obtained by Rasmussen and Painter[6] than those obtained by Cleaver[9], for example (Table 1). In the former experiments incubation times of up to 2 h were used, whereas times of only 10 min were used in the latter.

This dependence of the D_{37} values on the duration of incubation in labelled precursors makes it difficult to apply target theory to the results of these experiments, and of the experiments referred to in Table 1. In those instances in which target theory has been applied, the values obtained for the target dimensions and molecular weight can only be regarded as very rough approximations[7,10].

No difference was noted between the fraction of cells that were labelled in the irradiated and control regions of either cell type, even in autoradiographs which were deliberately over-exposed. These observations differ from those of Rasmussen and Painter[6] in which they observed that almost 100 per cent of the population in cultures of HeLa and of Chinese hamster cells were labelled after ultra-violet irradiation. This phenomenon of almost 100 per cent labelling has been interpreted in terms of a repair system which operates after irradiation with ultra-violet light[6]. The results described here indicate, however, that this repair mechanism does not operate in every type of mammalian cell, and is absent from both *L* and *FL* strains.

Since, in these experiments, no change in the fraction of labelled cells was detected, and the labelling time was too short for there to be any significant redistribution of the populations of cells in the various phases of the cell cycle during the experiments, the results shown in Fig. 1 are taken as representative of the response of DNA synthesis in *S* phase cells to ultra-violet light at 37° C over the dose range indicated, in both cell types.

The dose-response curve which has been obtained in the experiments described here appears to be genuinely multiphasic when determined under carefully controlled conditions of exponential growth and uniform temperature. A comparison between this dose-response curve and the one previously reported, for which irradiations were performed at room temperature and labelling at 37° C (9, Fig. 1), indicates that both procedures result in essentially the same dose-response curve. The results obtained for ultra-violet light are in contrast to those obtained for ionizing radiations by Smith[10] and by Manasek *et al.*[11]. These workers found that if both irradiation and labelling were performed at 37° C, the dose-response curve followed a single one-hit curve. The dose-response curve obtained when ionizing radiations are used may then be multiphasic only when irradiation and subsequent labelling are performed at different temperatures, whereas a multiphasic curve may be obtained after irradiation with ultra-violet light irrespective of temperature conditions.

These observations make it necessary to consider at least two main problems:

(1) The temperature conditions during irradiation and labelling do not seem to affect the shape of the dose-response curve for irradiation with ultra-violet light, whereas these conditions may affect the curve obtained when ionizing radiations are used. One possible explanation for this difference is that irradiations with ultra-violet light are brief; the highest flux in Fig. 1, for example, corresponds to only about 3·5 min irradiation. If cells are grown and labelled at 37° C, the precise temperature during irradiation is then unimportant. This is because there is insufficient time for the growth rate of the cells to respond to a brief change in temperature during the period of irradiation Irradiation with X-rays, however, involves periods of 30 min and longer, which is sufficiently long for the growth rate of the cells to respond to temperature changes. Consequently, during irradiation at room temperature with ionizing radiations the growth rate of the cells will fall from the normal rate at 37° C, and the radiation sensitivity may then be different from that of cells maintained at 37° C throughout.

(2) The second problem is that of finding an explanation for the precise shape of the multiphasic dose response curve obtained using ultra-violet light. A similar multiphasic curve has been obtained in a number of *in vivo* experiments with ionizing radiations[8,20–22], and in these cases temperature effects do not seem to afford a possible interpretation. Although many explanations have been offered for the shape of the dose-response curve, no definitive experiments have made it possible to choose between them, and in the case of *in vitro* irradiation with ionizing radiations temperature effects must be added to the list of possible explanations which have been discussed in detail elsewhere[1,2,4,6,9,20,22]. Temperature changes may not be the complete explanation for the shape of the dose-response curve, however, because a biphasic curve has been obtained by Mak and Till[23] from experiments in which cell cultures were maintained at 37° C throughout the experimental procedure.

A final point should be made, however, concerning the relationship between the dose-survival curves following irradiation with ionizing radiations or ultra-violet light and the dose-response curves for the inhibition of DNA synthesis by these radiations. The value of the D_{37} dose for the survival of cells irradiated in the *S* phase is about 200 rads, in the case of X-rays, or about 40 ergs/mm², for the flux of ultra-violet light[24]. If these values are compared with the D_{37} values shown in Table 1 for the inhibition of DNA synthesis, it is apparent that the dose range over which significant inhibition is observed

is one over which the surviving fraction will be much less than 1 or 2 per cent. Consequently, the major portion of the dose-response curve for the inhibition of DNA synthesis represents the residual DNA synthesizing ability of cells which are unable to recover from the effects of irradiation. This pathological condition may involve different processes to those which are involved in DNA synthesis in undamaged, viable cells. Such processes may involve, for example, the initiation of new growing points for the polynucleotide chains[7,25] or end addition of labelling molecules to the sites of damage[26].

PROLONGED WHOLE-BRAIN REFRIGERATION WITH ELECTRICAL AND METABOLIC RECOVERY

By PROF. ROBERT J. WHITE, DR. MAURICE S. ALBIN, DR. JAVIER VERDURA and GEORGE E. LOCKE

Section of Neurosurgery, Cleveland Metropolitan General Hospital and Western Reserve University, School of Medicine, Cleveland, Ohio

THERE is good evidence that the physical phenomenon of temperature reduction in itself confers protection on certain organs[1,2] during protracted periods of circulatory arrest, presumably by markedly curtailing intrinsic metabolic activity. While the brain *in situ* appears to enjoy this protection to a limited degree at moderately lowered temperatures[3,4], its response as an intact organ to extended periods of ischaemic refrigeration at temperatures approaching 0° C is not known. It is true that small tissue aggregates of brain incubated at 0·5° C for up to 24 h have been shown to be capable of resuming measurable, although reduced, metabolic activity on rewarming[5,6]. Unfortunately these and all *in vitro* studies of cerebral metabolism are limited because damaged tissue (in the form of slices or homogenates) is used[7], and because the experimental conditions necessarily prevent use being made of the intrinsic circulation of the tissues[8].

This article reports some experiments designed to examine the recovery properties of the whole brain following prolonged storage at 2·0 ± 1·0° C without circulation. The intrinsic cerebral circulation was utilized for rapid cooling, for rewarming and to provide metabolic support for the brain. During the period of refrigeration, the blood volume of the brain was filled by a non-cellular solution.

The canine brain, exposed within an isolated head preparation, was selected for the experimental model. The following parameters were examined: electrical activity, oxygen consumption and carbon dioxide production, and topographical appearance of the brain.

Dogs were anaesthetized with sodium pentobarbital and endotracheally intubated through a tracheotomy permitting mechanical ventilation following immobilization with gallamine triethiodide. Intra-arterial pressure measurements were made from a femoral artery. After mechanically fixing the head and body, all the muscles of the neck were surgically divided in a continuous ring at C_2 and the individual spinal muscles were scraped from the bony surface of C_2. The jugular veins and the carotid sheath structures were preserved. A laminectomy of C_1 and C_2 was performed, the dura opened and the anterior spinal arterie(s) destroyed. Both vertebral arteries were obliterated in their canals in C_1, leaving only the carotid arteries to provide circulation to the head. All scalp tissues were ablated and the entire dorsal surface of skull, except a thin bony strip over the sagittal sinus, was removed. The sagittal sinus was cannulated with a small polyethylene tube.

The isolated head preparation was differentially cooled following heparinization (2 mg/kg) utilizing a simple perfusion circuit incorporating a pre-calibrated Mark pump and a Mayo heat exchanger interposed between a cannulated femoral artery and bilateral metal 'T' cannulae in the carotid arteries. When intracerebral temperatures reached 20° C, the entire head was encased in a plastic reservoir filled with ice water to increase the efficiency of cooling. Within 20 min, and invariably before cardiac activity had ceased, brain temperatures of 6°–8° C had been achieved. The spinal cord was ligated and divided and the spinal column separated at C_2. The carotid arteries, previously closed behind the cannulae, were divided and the jugular veins and vagi severed. The isolated cephalic preparation was immediately perfused by means of its carotid cannulae with 250 c.c. of ice-cold heparinized Ringer's lactate solution, thus removing the remaining cerebral blood volume and rendering the cortical surface a pale white colour. The brain temperature was simultaneously reduced further to 3° C. The arterial cannula system was closed, the dura was opened over the brain and the isolated head was completely immersed in a special reservoir containing Ringer's lactate solution at 2° C. Two canine preparations were used for each of the following ischaemic refrigeration periods: 2, 4, 12 and 18 h; 1, 2, 8 and 15 days.

At a predetermined time, the isolated preparation was removed from the reservoir and connected by means of its cannula system to a large donor animal previously

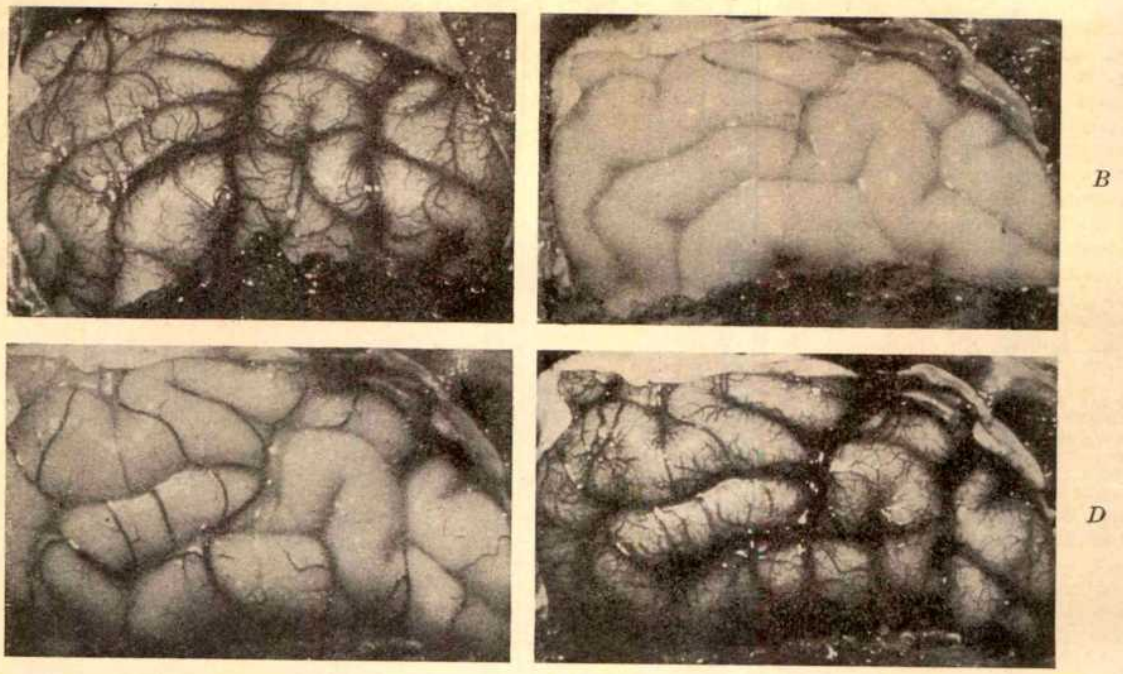

Fig. 1. Lateral view of the cerebral cortex of dog; (*A*) Normal morphology of cortex and vasculature prior to cooling. (*B*) Cadaveric appearance of brain surface following cooling and perfusate 'washout' of blood volume (intracerebral temperature 3° C just before ischaemic storage refrigeration). (*C*) The first appearance of blood in cortical arteries during initial donor perfusion rewarming. (*D*) Complete cerebral revascularization during late rewarming perfusion (intracerebral temperature 24° C). Note similarity of morphology of the cortical surface, arteries and veins of brain stored for 15 days with its pre-storaged (normal) appearance in (*A*)

anaesthetized with sodium pentobarbital and endotracheally intubated. The same simplified perfusion equipment was interposed between a cannulated femoral artery of the donor animal and the 'T' cannulae in the carotid arteries of the isolated head. The brain was gradually rewarmed by perfusing its cerebral circulation with donor blood at a temperature approximately 5° C higher than the intracerebral temperature. This temperature differential was consistently adjusted in an upward direction by altering the temperature of the donor blood during its passage through the heat exchanger. At intracerebral temperatures of 20° C, six electrodes were positioned in brain and connected to a Grass 'Polygraph' with electroencephalogram preamplifiers. Periods of 30–40 min were required to rewarm the brain to more than 30° C; at this temperature, blood samples were simultaneously removed from the arterial line and the jugular vein or the sagittal sinus for measurements of Po_2 and Pco_2.

Arterial pressures were continuously monitored within the aorta of the donor animal and the extracorporeal perfusion line. Temperatures were recorded from the oesophagus of the donor animal, from the perfusion line distal to the heat exchanger, and from the brain by means of suitable thermo-probes. Precalibration of the Mark pump provided satisfactory control of perfusion flows which, for cooling, were gradually reduced from 120–100 c.c./min to 40–50 c.c./min. For rewarming, the rate of flow was gradually increased, depending on the brain temperature and the pressure in the perfusion line. At the beginning, the flow rate was of the order of 40–50 c.c./min, and was increased to 150–200 c.c./min as brain temperatures reached 30° C or higher in order to maintain perfusion line pressures of between 100–150 mm mercury systolic.

In all storage preparations, including the two refrigerated for 15 days, excellent revascularization of brain was observed during rewarming perfusion (Fig. 1). The anatomical differentiation of cortical arteries and veins was readily apparent as the pale white colouring of the cool brain gave way to the more normal appearance of the cerebral cortex with active perfusion by warm donor blood (Fig. 1). Cerebral oedema became manifest in each brain during the rewarming cycle, gradually developing with increases of temperature above 20° C. Oedema was most pronounced in those brains stored for the longest periods of time. The onset of brain oedema could be delayed or temporarily reduced by introducing small

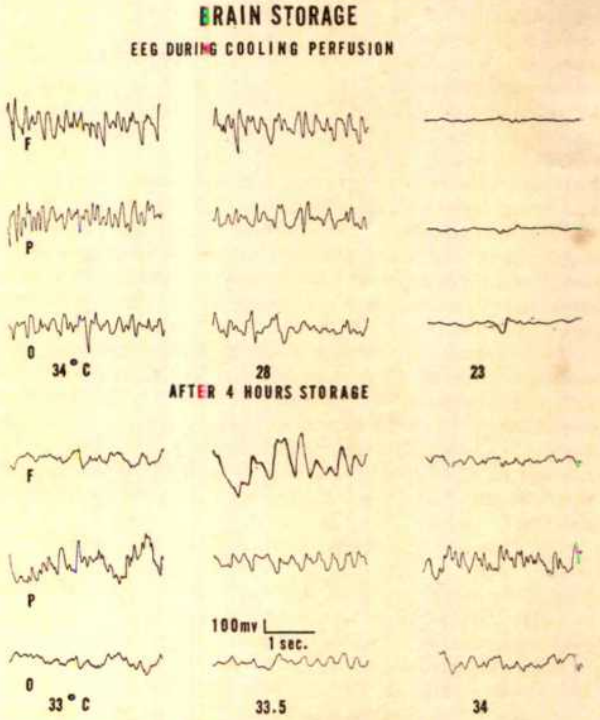

Fig. 2. Electro-cortical brain activity from paired frontal, parietal and occipital surface electrodes during cooling perfusion and on rewarming after 4 h of hypothermic storage. Note the isoelectric activity in all leads at 23° C. On rewarming, the tracings at 34° C show reduced activity in the frontal and occipital lobes. The parietal lobes, on the other hand, contain good activity of about 10 c/s at 30–50-mV amplitude with some large slow spikes of 150-mV appearing

amounts of urea (750 mg) directly into the arterial perfusion line. (Presumably the urea led to an acute increase in the osmolality of the perfusion blood, thus producing a diffusion gradient across the blood-brain barrier.)

With brains stored for 2 h and 4 h, cerebral electrical activity was restored at intracerebral temperatures of 22° C or more (Fig. 2). Prolonged maintenance perfusion of the rewarmed brain (34° C) for more than 6 h invariably resulted in the disappearance of electroencephalographic activity and the development of irreversible cerebral oedema. Brains refrigerated for periods of time between 4 and 12 h were not examined, and no recognizable cerebral electrical activity has been recorded from brains stored for 12 h or more. Furthermore, pupillary light reflexes could easily be elicited, and persistent rhythmic gasping observed in the isolated heads refrigerated for 2 h and 4 h; these were not observed after 12 h or more of ischaemic hypothermia.

The resumption of metabolic activity by the refrigerated brain was indicated by the development of significant arterio-venous O_2 and veno-arterial CO_2 differences on rewarming. Isolated heads stored for 12 h or less (4 h and 2 h) averaged A-Vo_2 and V-Aco_2 differences of 5·1 vol. per cent and 4·1 vol. per cent respectively at 34° C. Since samples were taken from the jugular vein, these values are indicative of cephalic and not of pure cerebral metabolism. Brains stored for longer periods (18 h, 1, 2, 8, 15 days) demonstrated substantially identical values for A-Vo_2 and V-Aco_2 differences, which averaged 2·6 vol. per cent and 2·3 vol. per cent respectively when measured at 30° C. These values are based on sagittal sinus blood, and thus they represent oxygen consumption and carbon dioxide production after rewarming across the brain alone.

While it can scarcely be argued that the brain is normal when rewarmed after prolonged hypothermic storage, these investigations indicate that the intrinsic circulation of brain remains intact, even after 15 days of refrigeration, permitting reconstitution of an active, functioning cerebral arterial and venous circulation. Brains refrigerated for short periods of time (up to 4 h) demonstrate that cerebral tissue stored at extremely low temperatures (2°–3° C), and when entire blood volume has been replaced by a non-cellular perfusate, will reconstitute a recognizable electroencephalographic pattern on haematogeneous rewarming. Examination of haematoxylin- and eosin-stained microscopic sections of stored and rewarmed brain revealed that both glial and neuronal cellular elements are preserved.

This investigation was supported by research grants from the National Institutes of Neurological Diseases and Blindness. The technical assistance and advice of Dr. Leo Massopust and Mr. Ronald Meder are gratefully acknowledged.

PROGESTAGEN INHIBITION OF NORMAL SEXUAL BEHAVIOUR IN THE MALE GUINEA-PIG

By Prof MILTON DIAMOND
Department of Anatomy, University of Louisville School of Medicine, Louisville, Kentucky

LIKE the female of many species, the female guinea-pig, when injected with androgen, is easily induced to display male-like sexual behaviour[1]. High progesterone levels, however, resulting from pregnancy, pseudo-pregnancy or exogenous sources will protect the female from this 'induced masculinization'[2,3]. These findings raise questions as to possible effects of progesterone on normal males. Will progesterone or synthetic progestagens inhibit masculine sexual behaviour in the male as well as in the androgen-treated female? How do the effects of progestagen treatment compare with those of castration? These questions are of practical, as well as theoretical, interest in view of present-day tests of progesterone and progesterone-like substances as male contraceptives[4]. With non-standardized indices of behaviour some reports indeed indicate that progesterone can affect sexual performance[4,5].

To answer these questions, sixty-one mature male guinea-pigs 6–12 months old kept in individual cages were observed and tested with an oestrous female for a 10-min period each week. Observations were continued through three 10-week periods constituting respectively a control phase, an experimental phase, and a recovery phase.

During the control phase, all subjects were tested and handled in a similar fashion in order to obtain a base line of sexual performance for each animal. The experimental phase made it possible to observe the immediate effects of the various treatments. To prepare for this phase (within 6 h subsequent to the tenth test of the control phase), animals were assigned to one of six groups. Animals assigned to three of these groups were castrated. Beginning the following day, each subject in group 1 (progesterone-intact) was given two 25-mg injections of progesterone in cotton seed oil with 10 mg injections daily thereafter throughout the experimental phase; group 2 (MPA-intact) was given the same dosage of the synthetic progestagen 'Depo-provera', a brand of medroxyprogesterone acetate (MPA); group 3 (progesterone-castrate) was given the same dosage of progesterone; group 4 (progesterone-TP-castrate) was given the same dosage of progesterone with the simultaneous addition of 5 mg of the androgen testosterone propionate (TP) on the first day and 1 mg daily thereafter. This dosage of TP has been shown to be sufficient to maintain precastration levels of sexual activity in male guinea-pigs[6] and permits consideration of behavioural effects due to the interactions of hormones in known proportions. This would not be possible in intact animals with individually varying androgen output. Groups 5 and 6 served as intact and castrate controls respectively. Animals in these groups were given two initial 0·5 ml. and subsequent 0·2 ml. daily injections of cotton seed oil, the injection vehicle. Tests during the recovery phase indicated the nature and duration of post-treatment behaviour characteristics. During this phase all injections of progesterone and MPA were discontinued and the castrate groups (3, 4 and 6) received replacement

dosages of testosterone propionate, 5 mg on the first day and 1 mg daily thereafter. The intact groups (1, 2 and 5) received equivalent dosages of the injection vehicle. Injectates were uniformly prepared to contain 50 mg hormone/ml. oil. All injections were given intramuscularly daily and administered alternately into the right and left gluteal and hamstring regions.

The behaviour characteristics recorded included sniffing, nuzzling, mounting, intromission and ejaculation. Each of these components contributed a weighted value to a total sex score. (These behaviour components and scoring procedures have already been described elsewhere[6,7].)

The differences among the groups were statistically significant. During the experimental phase all groups except control-intacts showed marked and significant declines in sexual activity (Table 1). For most groups, an immediate decrease was evident. Between the final test of the control phase and the first test of the experimental phase (an interval of 1 week; 100 mg of progestagen) the sex score of the control-castrate group declined from 4·7 to 1·7, that of the progesterone-castrate group from 5·2 to 1·4, that of the progesterone-TP-castrate group from 4·7 to 1·8, and that of the intact group receiving MPA declined from 5·2 to 1·4. The progesterone-intact group dropped less, but significantly, from 6·3 to 3·4. At the end of the following week return toward control levels was seen, but after that, through the remainder of the experimental phase all groups except the control-intact showed a downward trend in their level of sexual activity.

Table 1. HORMONAL INHIBITION OF MALE SEXUAL BEHAVIOUR

Group	*N*	Sex score I Control phase	II Experimental phase	III Recovery phase	Significance* Phase I versus Phase II	Phase II versus Phase III
Control-intact	14	4·9	4·3	3·9	N S.	N.S.
Progesterone-intact	11	5 5	2·9	3·6	0·005	0 025
MPA-intact	8	4·1	2·1	2·4	0·01	N.S.
Control-castrate	10	5 1	1·9	3·6	0·005	0 025
Progesterone-castrate	7	5·1	1 6	3 8	0·01	0·01
Progesterone and TP-castrate	11	4·8	2·1	2 4	0 005	N.S.

* Wilcoxon matched-pairs signed-ranks test.

Over-all findings from intact and castrate control groups were as expected; no significant effects due to the placebo were seen in intact animals, but castration significantly reduced sexual activity. In the critical experimental groups it was obvious that both progesterone and the synthetic progestagen, MPA, are capable of inhibiting normal masculine sexual behaviour to an extent comparable with castration. The effect of castration and progesterone combined produced the largest drop in activity but this was not statistically more injurious to libido than was either treatment alone. The results gained with the castrate group receiving simultaneously androgen and progesterone showed that 1 mg of testosterone daily was generally insufficient to overcome the inhibiting effect of 10 mg of progesterone daily.

The decline in sexual behaviour scores generally reflects a decrease in incidence of the higher components of the male sexual pattern, that is, mounting, intromission and ejaculation. Ejaculation frequencies were most markedly affected.

In all experimental groups at least a 50 per cent reduction was found in the frequency of ejaculation. Groups injected with progesterone or medroxyprogesterone acetate experienced a decrease in ejaculations of more than 75 per cent.

During the recovery phase, the cessation of progestagen treatment, replacement therapy with TP, or both were followed by a significant return toward control phase levels of sexual behaviour (Table 1). In the progesterone-intact and the progesterone-castrate groups a rise toward normal levels of sexual activity was evident within a week. Cessation of treatment with MPA was not followed by a similar recovery until the last 3 weeks of the investigation. Thus, although both progesterone and MPA are capable of inhibiting male sexual activity, the effects of progesterone seems relatively slow to appear and quick to disappear, while the effects of MPA develop quickly and persist longer.

No group displayed as high a level of sexual performance during the recovery phase as it had during the control phase. This may not be unexpected for the progestagen-treated animals where a longer interval for recovery might be needed. Concerning the control males, Grunt and Young[6], Antliff and Young[8] and Jakubczak[9] also previously noted a decrease in the sexual behaviour scores of normal guinea-pigs during long-term experiments. They suggested that this is possibly related to advancing age. Analysis and comparison of the components of the sexual pattern for the recovery period with those found during the control phase reveal that these differences are qualitative as well as quantitative. While the low frequency of mounting seen during the experimental phase returns toward control phase levels, the frequency of intromission and ejaculation remains low. These latter behaviour components have been shown to be more labile than mounting when tested in respect to such factors as age[9] and castration and androgen therapy[10,11]. A differential sensitivity in the neural tissues mediating these behavioural patterns has been postulated.

Histological studies of the testes of the intact groups 1, 2 and 5 were conducted within a week following the end of the recovery phase. In addition, the last day of the experimental phase, testes were removed from 3 sets of 2 males each, treated in a manner identical to the three intact groups. Thus comparisons of gonads immediately after the experimental treatment and after recovery were possible without disturbing the actual experimental animals during the test sequence.

The testes of males treated with progesterone for 10 weeks showed few histological differences from controls. Nevertheless, the mean weight of the testes obtained from the progesterone-treated males was 2·79 g while that from the control males was 3·99 g. A substantial decrease in testes weight due to progesterone has also been reported for humans[4]. Despite this weight loss, as in humans[4], the tubular contents and interstitial cells appear unaffected by therapy except for a decrease in the absolute number of mature sperm. This is in contrast to findings in the rabbit[5] and ram[12], where general disorganization and degeneration of tubule contents have been reported.

Testes from males treated for 10 weeks with MPA, on the other hand, are severely affected. The mean weight of the testes from this group was 1·25 g; less than half that of the controls. Under the microscope these testes showed general disorganization of the tubules and a lack of mature spermatozoa. Occasional tubules were spared, however, and all stages of spermatogenesis could be seen. Mature spermatozoa could be found in the epididymides of all animals. Following the recovery phase of 10 weeks no significant differences in testis weight or histological appearance were discernible between the groups. Ericsson and Dutt[12] report similar effects of MPA on the ram testis.

These data indicate that progesterone and MPA are both capable of temporarily reducing the level of sexual performance in the male guinea-pig. It is not clear from these results where these progesterones act to bring about this inhibition. The seeming lack of serious effect of progesterone on the testes found in these experiments (and reported elsewhere for humans[4]) implies that we are dealing either with a pituitary feed-back problem or a direct nervous system effect. Additional experiments will be needed to clarify this point.

In view of its ability to inhibit androgen-induced masculine behaviour in the progesterone-rich female[2,3] as well as in the male, progesterone is thus seen to be capable of affecting sexuality in both sexes so that

androgen is ineffective in its role of activating the neural tissues mediating masculine sexual behaviour patterns. With recent findings[13–15], confirming the unique part played by androgen in the differentiation of the hypothalamus with respect to structuring both male and female sexual behaviour, it is perhaps not surprising that a single hormone, progesterone, is capable of antagonizing an androgenic action in both sexes.

Progesterone, testosterone propionate and 'Depo-provera' were supplied through the generosity of Dr. S. S. Stubbs of the Upjohn Company, Kalamazoo, Michigan. Appreciation is extended to Barbara Tullis, Herbert Cook and Milton Palanker for assistance at various times during the course of this study.

This investigation was supported by a U.S. Public Health Service research grant from the National Institutes of Health.

BEHAVIOURAL SIGNIFICANCE OF HYPOTHALAMIC TEMPERATURE-SENSITIVE CELLS

By Dr. H. J. CARLISLE*

Departments of Psychology, and Physiology and Biophysics, University of Washington, Seattle

THE existence of thermally sensitive neurones in the hypothalamus has been inferred since the classic demonstration that heating the pre-optic region in the cat produces the appearance of sweat on the foot pads and panting[1]. Furthermore, electrical stimulation of this region leads to cutaneous vasodilatation and a decrease in rectal temperature[2]. These neurones, considered physiologically important in the central control of body temperature, have been shown to be sensory by single-unit investigations in which an increased frequency of firing accompanied local hypothalamic heating and a decrease accompanied cooling[3]. A change in the temperature of the blood perfusing the hypothalamus might thus provide a stimulus for activation of thermoregulatory mechanisms[4].

It has not been clear, however, whether sensations of warmth or coldness accompany activation of these cells. Such perceptual alterations might be revealed in a number of ways[5,6], but the participation of cutaneous receptors is hard to rule out. Vasodilatation, which accompanies hypothalamic heating, and vasoconstriction, which accompanies cooling, would be expected to affect cutaneous temperature.

In recent investigations of behavioural temperature regulation, rats were trained, in a cold environment, to press a lever to obtain radiant heat[7]. The rate of response in these investigations varied inversely with the ambient temperature. This technique has been used in the present investigation in conjunction with hypothalamic heating to establish a situation in which temperature-dependent behaviour can be observed while hypothalamic and peripheral temperatures are clearly separated.

Bilateral heating coils and a thermistor were chronically implanted by stereotaxic means in the hypothalamus of six rats. The maximal diameter of each heater was 1·0 mm, and the distance between heaters 1·5–3·0 mm. Heat was generated by the passage of direct current while the degree of hypothalamic heating was monitored by a thermistor (*VECO* 32*A*7) placed less than 1 mm from one heater. In some cases, subcutaneous thermistors were also placed at the nape of the neck. Electrical connexions were made with Winchester plugs, the sockets of which were fixed to the cranium after implantation of heaters and thermistor.

The unrestrained animals were placed in a temperature-controlled chamber and coupled to the recording equipment with flexible cables which permitted heating and recording over extended periods. The rats were trained to respond to cold ambient temperatures by pressing a lever that turned on an infra-red heating lamp. The intensity and duration of heat re-inforcement obtained for a single lever-press could be varied by the experimenter as desired. Training was continued until stable rates of bar-pressing were obtained (at least three sessions of 7 h each). The hypothalamus was then heated by way of the heating coils while the animal pressed the lever to obtain peripheral radiant heat.

Four animals with anterior hypothalamic-preoptic placement of heaters showed a decrease in the rate of responding when this region was heated to 40·0°–40·5° C for 20–30 min. The percentage decrease in rate of responding during the initial heating period, in comparison to the period immediately before heating, was 48, 63, 72 and 89 per cent for these rats. Increased rate of responding during hypothalamic heating was never observed. Two animals with more posterior placements (level of the paraventricular nuclei) showed no consistent behavioural effect during central heating.

When the experiment was repeated during subsequent sessions a diminished effectiveness of central heating was observed. That is, hypothalamic heating produced a decrease in rate of responding for peripheral heat, but not to the extent previously seen. This may be attributed to tissue damage as a result of heating[5], or to experience in this situation.

An activation of heat-loss mechanisms was evident in addition to the behavioural effect of central heating. Hypothalamic temperature fell below the pre-heating level on cessation of central heating, indicating a decrease in whole-body heat content. This decrease could not be entirely due to the diminished rate of responding, since the magnitude of the heat-loss was greater than when the animal was exposed to the same ambient temperature with no opportunity to obtain peripheral heat (during the extinction period).

These results are illustrated in Figs. 1 and 2, which were obtained from the animal having the most marked effect from central heating. Fig. 1 shows the suppression of responding during the period when the hypothalamus was heated to 40·5° C. Hypothalamic temperature fell

* Present address: Department of Psychology, University of California, Santa Barbara, U.S.A.

to 34·2° C on cessation of heating, a decrease from the pre-heating value of 38·3° C. The amount of heat lost to the environment during hypothalamic heating should be compared with the amount normally lost when temperature-regulating mechanisms are intact. It should be noticed that during extinction, when the heat lamp was disconnected from the circuit, hypothalamic temperature decreased only 0·4° C in the first 20 min. The temperature decrease during hypothalamic heating was 4·1° C for a comparable period. Hypothalamic heating therefore increased heat loss more than tenfold over that observed during exposure to the same ambient temperature. From previous investigation[6], it can be inferred that the extent of heat loss observed in this experiment was due to peripheral vasodilatation and a decrease in heat production.

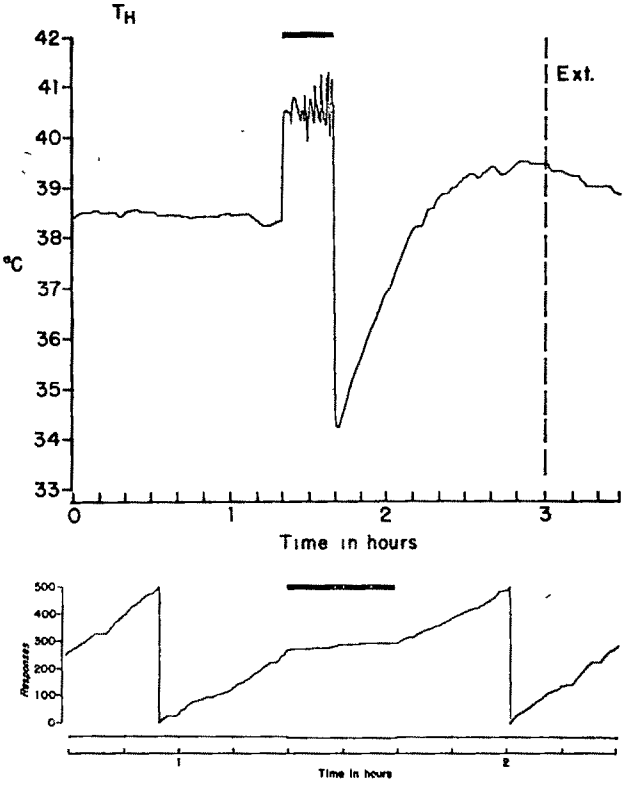

Fig. 1. Suppression of responding for peripheral heat during local hypothalamic heating (black bar). T_h, Hypothalamic temperature. Ambient air temperature, 0° C. Reinforcement, 2 sec at 200 W. Average temperature during hypothalamic heating is 40·5° C. Rate of responding is indicated by the slope of the curve in the lower record. The dotted line indicates the point at which the heat lamp has been disconnected (extinction period). Note that, although the lower time scale is expanded in length, it corresponds with the upper scale

Immediately after the heating period, the rise in hypothalamic temperature is too fast to be due to heat reinforcement alone and must therefore reflect a reinstatement of peripheral vascular tone and metabolic heat production. A rebound effect is evident in that hypothalamic temperature rises to 39·5° C at 70 min after cessation of heating, a level higher than that observed normally. The animal groomed and sniffed at various parts of the cage during heating, and a number of bar-presses were apparently made inadvertently during this activity. There was no sign of discomfort as judged by the behaviour of the animal.

When the experiment was repeated over a period of several days, the effect of hypothalamic heating on behaviour diminished, as shown in Fig. 2. Hypothalamic heating still decreased the rate of responding but not to the extent previously seen. Subcutaneous temperature fell steadily, reaching 29·8° C at the end of the 30 min

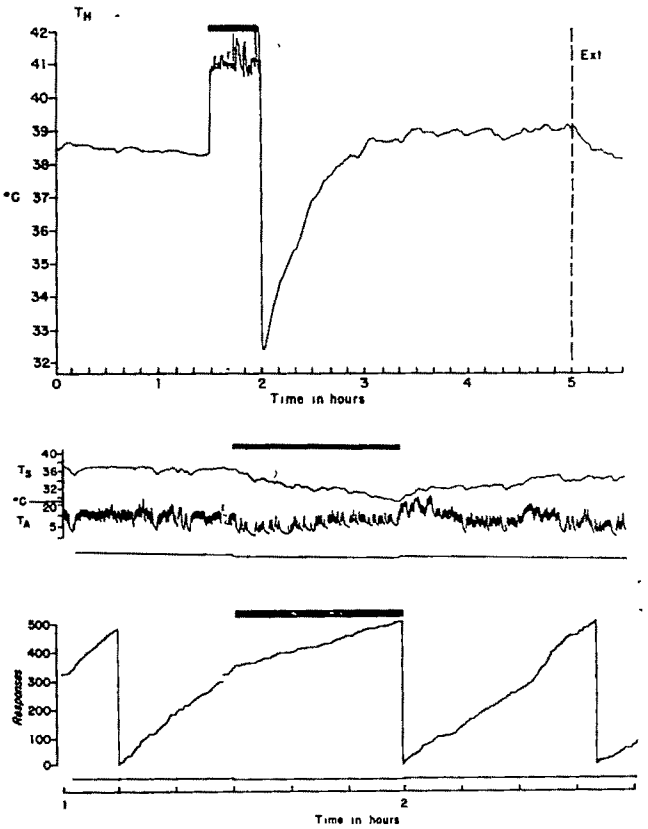

Fig. 2. Decrease in rate of responding for peripheral heat during local hypothalamic heating. T_s, Subcutaneous temperature; T_a, temperature measured by thermistor placed between heat lamp and the animal (each reinforcement produces a sharp increase in temperature, which then falls slowly until the next reinforcement). Ambient temperature, 0° C. Reinforcement, 2 sec at 200 W. Average temperature during hypothalamic heating is 41·0° C. The lower time scale refers to the lower records and, although expanded in length, corresponds to the upper record also

heating period. The rate of fall of subcutaneous temperature, and the final low value attained, would seem to contradict a strong thermal drive contribution from cutaneous receptors during hypothalamic heating. Rate of responding should actually increase during the heating period to compensate for falling peripheral temperature if these receptors are influential.

The relatively large size of the heaters produced hypothalamic damage, and central heating may have further increased the amount of this damage. Nevertheless, the animals maintained normal body temperature in a neutral environment, and worked for heat in a cold environment. Heater implantation and hypothalamic heating, therefore, did not preclude either temperature regulation or adaptive responsiveness. It is concluded that, under the conditions used here, an animal may respond as though the environment were warm if the hypothalamus is warm, even though deep body and subcutaneous temperatures may be low.

INFECTIVITY OF GROSS AND RAUSCHER LEUKAEMIA VIRUSES AND THEIR NUCLEIC ACIDS

By Dr. ESTHER F. HAYS and PAUL F. ALPERT

Laboratory of Nuclear Medicine and Radiation Biology, Department of Biophysics and Nuclear Medicine, and Department of Medicine, School of Medicine, University of California, Los Angeles

TWO reports[1,2] have demonstrated infectivity of ribonucleic acid extracted from tissues infected with mouse leukaemia viruses, the Graffi agent and the Maloney virus. The present investigations were undertaken to reproduce these observations using the viruses of Gross and Rauscher; however, they failed to do so. Cell-free extracts of neoplastic tissue from mice with leukaemia induced by Gross and Rauscher viruses were found to reproduce the disease in inoculated mice, while nucleic acids extracted from the same neoplastic tissues did not result in disease.

The mice used in these experiments were from *AKR/J* and *C3HeB/FeJ* inbred strains maintained in this laboratory. The Gross virus used was passage *A*. This was supplied by Dr. Ludwik Gross of the Bronx Veterans Administration Hospital, Bronx, New York, in the form of a *C3H* mouse with virus-induced leukaemia, and has been maintained in our laboratory by inoculation of suckling mice with extracts prepared by Gross's method[3] without filtration. The preparations for virus inoculation and nucleic acid extraction were from animals developing lymphoma after the fifth such passage.

The Rauscher virus (*P*-805) was generously supplied by Dr. Frank J. Rauscher of the National Cancer Institute. It was from a crude 10 per cent extract of spleens collected from *BALB/c* mice 28 days post-intraperitoneal inoculation of virus. This material was shipped in the frozen state and stored at −70° C until used. Animals with Rauscher disease for use in these studies were inoculated when 1–2 days old with *P*-805 virus in an undiluted form. All the tissue extracts containing Rauscher virus were prepared by Gross's method[3] without filtration; nucleic acid preparations were made from the same animals with disease developing after inoculation of the original spleen extracts obtained from Dr. Rauscher.

Homogenates of tissues from animals with either Gross virus-induced leukaemia, or Rauscher disease, were used for extraction of the nucleic acid. The deoxyribonucleic acid (DNA) was prepared by the method of Kirby[4] with cold phenol and *p*-amino salicylic acid. To minimize nuclease activity 5×10^{4} M versene (disodium ethylenediamine tetraacetate) was added to the tissue homogenate and the whole procedure was carried out at < 4° C. To remove the ribonucleic acid (RNA) from these preparations, 100 per cent isopropyl alcohol was added to the phenol extract to give a 20 per cent alcohol content by volume. This precipitated the RNA. After centrifugation for 1 h at 16,000*g*, the sedimented RNA was removed and the alcohol content of the supernatant was raised to 37·5 per cent to precipitate the strands of DNA. The DNA was redissolved and precipitated two or more times and dissolved in saline or phosphate buffer for inoculation. The final material used for injection contained DNA in concentrations of 800 μg/c.c. as measured by the diphenylamine reaction. RNA contamination was 140 μg/c.c. as measured by the orcinol test. The control material was made by treating this solution with DNase (20 μg/c.c. for 20 min) at room temperature.

The RNA was prepared by the cold phenol method of Gierer and Schramm[5]. The final RNA concentrations in these inocula were 900–1,000 μg/c.c. The control inocula were incubated with RNase (20 μg/c.c.) for 20 min at room temperature. These RNA preparations had no measurable DNA contamination.

The cell-free extracts were administered intraperitoneally in 0·1–0·2 ml. amounts in 1–3-day-old mice of both strains. The nucleic acid preparations were given by three routes: (1) intraperitoneal (0·2 ml.) in animals 1–3 days old; (2) intrathoracic in 0·05 ml. amounts in 1–2-day-old animals; (3) intracerebral in 0·02 and 0·03 ml. volumes in new-born and 22–29-day-old animals.

Extracts of tissues from animals with Gross virus-induced leukaemia inoculated into suckling *C3HeB* mice produced at 2–4 months of age a lymphoblastic leukaemia in 100 per cent of the animals. Pathologically the virus disease resembled closely the spontaneous *AKR* lymphoma; the thymus was always involved as were the liver, spleen, lymph nodes, Peyer's patches and kidneys. The lymphoid tissue was in most instances completely replaced by lymphoblasts and cellular infiltrates were seen in the liver and kidneys. Transplantation of these virus-induced leukaemias was accomplished in isogenic strains. Adult *C3HeB* mice inoculated with viable cells developed leukaemia in 3–4 weeks.

Rauscher virus preparations when inoculated intraperitoneally into 0·1 c.c. amounts into suckling *AKR* and *C3HeB* mice produced disease in 100 per cent of the animals in 15–31 days. This disease was like that described by Rauscher[6] and was characterized by hepatosplenomegaly but no striking lymph node enlargement. The animals were all anaemic with marked anisocytosis, poikilocytosis and basophilia of the red cells. The peripheral blood nucleated cell count was 25,000–100,000/mm³. The differential count revealed many nucleated red cells in all stages of development as well as undifferentiated cells which were fragile and frequently smudged on the coverslip blood film. Microscopically the spleens were infiltrated with these same cell types in almost equal numbers, that is, erythroid precursors and undifferentiated cells. The immature cells resembled reticulum cells. The spleen also contained large areas of haemorrhagic necrosis. The lymphoid tissue of the spleen was virtually absent. The liver was heavily infiltrated with the erythrocyte precursors and reticulum cells; again each infiltrate was composed of equal percentage of both cell types. Lymph nodes were usually normal but some showed infiltrates of the abnormal cells found in the liver and spleen. The thymus demonstrated marked cortical atrophy. Morphologically the disease could be called an erythroid leukaemia.

However, when transplantations were carried out with viable cells obtained from the liver and spleen, and using isogeneic strain combinations, 10^{7} cells inoculated subcutaneously in suckling mice, or by either route in adult animals, did not result in local tumours or generalized disease. This was in marked contrast to similar cell transfers made in adult animals with Gross virus-induced leukaemic cells, where all the inoculated adult animals developed local tumours after subcutaneous inoculations and generalized disease 21–30 days after intraperitoneal inoculation of 10^{7} cells.

The nucleic acids were prepared by the methods already described from tissues of animals with Gross and Rauscher virus-induced leukaemias. As can be seen from the results summarized in Tables 1 and 2, inoculation of mice with the nucleic acid did not result in disease. Cell-free extracts of the same tissues used for nucleic acid extraction were given to suckling mice as a bioassay for the presence of virus in the tumours. All these extracts had potent oncogenic properties as indicated in Table 3. In each instance the disease produced was characteristic for the virus inoculated. All the animals given nucleic acid and their controls were killed 7 months later, a time well beyond the latent period of disease produced by these viruses when administered to suckling mice.

Table 1. RESULTS OF INOCULATION OF DNA EXTRACTED FROM TISSUES OF ANIMALS WITH GROSS AND RAUSCHER VIRUS-INDUCED NEOPLASMS

Mouse strain	Material inoculated*	No. neoplasms/No. mice
AKR	DNA (Rauscher)	0/22
AKR	DNA (Rauscher) + DNase	0/20
C3H/eB	DNA (Rauscher)	0/13
C3H/eB	DNA (Rauscher) + DNase	0/23
C3H/eB	DNA (Gross)	0/41
C3H/eB	DNA (Gross) + DNase	0/39

* Inoculations made intracerebrally at 22–30 days, or intrathoracically at 1–3 days.

Table 2. RESULTS IN INOCULATION OF RNA EXTRACTED FROM TISSUES OF ANIMALS WITH GROSS AND RAUSCHER VIRUS-INDUCED NEOPLASMS

Mouse strain	Material inoculated*	No. neoplasms/No. mice
AKR	RNA (Rauscher)	0/29
AKR	RNA (Rauscher) + RNase	0/30
C3H/eB	RNA (Rauscher)	0/18
C3HeB	RNA (Rauscher) + RNase	0/16
C3H/eB	RNA (Gross)	0/60
C3H/eB	RNA (Gross) + RNase	0/23

* The inoculation routes were intracerebral at 1 or 25 days intrathoracic at 1–3 days and intraperitoneal at 1–3 days.

Table 3. RESULTS OF INOCULATION OF CELL-FREE EXTRACT OF TISSUES OF ANIMALS WITH GROSS AND RAUSCHER VIRUS-INDUCED NEOPLASMS

Mouse strain	Material inoculated*	No. neoplasms/ No. of mice	Latent period (days)
AKR	Rauscher	20/20	7–28
C3H/eB	Rauscher	9/9	12–21
C3H/eB	Gross	9/9	90–150

*All inoculations were given intraperitoneally to 1–2 day old mice. All extracts tested were from tissue used to make the nucleic acid preparations.

The findings of these investigations demonstrate the high degree of infectivity of cell-free extracts of tissues of animals with both Gross and Rauscher viral leukaemias, when inoculated into suckling mice of the *AKR* and *C3HeB* strains. The disease produced is characteristic for each virus. These agents are representative of two distinct classes of leukaemia virus based on the type of disease produced. The Gross virus results in a lymphoid neoplasm with cellular homogeneity which has a 2–4-month latent period and when it develops is readily transplanted by cells to susceptible hosts. The Rauscher disease (developing 2–4 week after inoculations) is characterized by a proliferation of erythroid and reticulum cells which are seen in the spleen, liver and peripheral blood. This disease is not transmitted by cells in that cell inoculation of adult mice does not result in local tumour formation, or generalized disease. The phenomenon of lack of development of solid cell-transmitted tumours is similar to observations in Friend virus-induced leukaemia, which closely resembles the Rauscher disease, where it was found that successful grafting only occurred late in the disease when the liver and spleens were massively infiltrated with leukaemic cells[7]. The lack of transplantability of cells of the early disease suggests that the initial disease characterized by the dual infiltrate is a pre-neoplastic state characterized by a cellular reaction to infection with the virus rather than a true neoplasia.

Nucleic acids extracted from these same neoplastic tissues did not produce disease in inoculated hosts. This lack of infectivity of nucleic acids could have been the result of nuclease activity during preparation, or after administration of the nucleic acids or to a physical alteration of the nucleic acid molecule resulting from the extraction procedure *per se*. The intracerebral route was used to minimize nuclease activity, and confidence in the phenol method of extracting infective nucleic acid from virus-infected tumour tissues was gained from results of previous experiments where DNA prepared from polyoma virus-induced tumours was shown to be highly oncogenic when administered to suckling mice by the intrathoracic route[6]. Despite this finding, a fundamental alteration of these viral nucleic acids resulting from their extraction by phenol would seem to be a likely explanation for the observed loss of infectivity. Their large helical RNA, much less stable than polyoma DNA, was probably broken into smaller fragments which were not infectious, for as Rubin[9] has suggested, the avian and murine leukaemia viruses are probably large RNA viruses.

These observations of loss of infectivity in nucleic acid preparations indicate a similarity of the Gross and Rauscher viruses to the larger, more complex animal viruses (poxviruses, herpes viruses and myxoviruses) from which infectious nucleic acid has not been completely extracted. In the case of myxoviruses, Maassab[10] has reported extraction of infectious RNA from influenza virus-infected cells, but not from preparations containing only virus. His work, however, has not been confirmed. Careful studies of Rous sarcoma virus by Weil *et al.*[11] could not demonstrate infectious RNA. This virus is a large RNA virus which like the leukaemia viruses is formed at the cell membrane[9]. A difference between the Gross and Rauscher viruses and those of Maloney and Graffi, from which infective nucleic acid has been extracted with methods similar to those reported here, is demonstrated by this investigation. The positive results of these two investigators might be explained by slight differences in the technique used in the extraction, or by contamination of their preparations with virus.

Cell-free extracts of tissues of mice with leukaemia induced by Gross and Rauscher viruses were found to be highly effective in producing the specific disease characteristic for each virus when administered to suckling *C3HeB/FeJ* mice. Nucleic acids extracted with phenol from the same neoplastic tissues failed to cause disease. These results suggest that the nucleic acid of these two classes of mouse leukaemia viruses is not phenol extractable.

These studies were supported by a contract between the Atomic Energy Commission and the University of California.

ATTEMPTS TO INDUCE LEUKAEMIA BY INCUBATION OF MOUSE THYMUS CELLS WITH LEUKAEMIC CELL NUCLEIC ACID

By DR. ESTHER F. HAYS

Laboratory of Nuclear Medicine and Radiation Biology, Department of Biophysics–Nuclear Medicine, and Department of Medicine, School of Medicine, University of California at Los Angeles

PREVIOUS investigations carried out in this Laboratory have shown that nucleic acids extracted from cells of leukaemic *AKR* mice and inoculated into new-born animals resulted in an increase of the incidence of leukaemia of host type in $(AKR \times C3H)$ F_1 hybrid mice[1]. Investigations using labelled DNA[2] have shown that this macromolecule can traverse the cell membrane *in vitro*, and Weil[3] has shown *in vitro* incorporation of viral DNA

into cells, utilizing hypertonic treatment to alter membrane permeability. The present study was undertaken to add to the previous *in vivo* investigations by attempting to produce *in vitro* leukaemic transformation of normal thymus cells. Two approaches were undertaken: (1) incubation of normal cells with leukaemic cell nucleic acid and inoculation into neonatal hosts of a low incidence leukaemia strain; (2) incubation of normal cells with leukaemic cell nucleic acid in hypertonic medium and inoculation into thymectomized adult animals with regenerating thymus grafts. The latter approach was used because of the well-known but poorly understood relationship of the thymus to the development of spontaneous leukaemia in mice. It was reasoned that the regenerating graft might be populated with the inoculated, nucleic acid treated cells, these cells then being in an environment more conducive to leukaemogenesis.

Most of the mice used in these studies were from inbred colonies of *C3HeB/Fe* and *AKR/J* mice maintained in this laboratory. However, the host animals in the second experiment were *AKR/J* females obtained directly from the Jackson Memorial Laboratory, Bar Harbor, Maine. The animals were fed Wayne 'Lab-Blox' and water *ad libitum* and housed in plastic boxes with white pine shavings. The leukaemia incidence in our *AKR/J* colony is 70–80 per cent. No leukaemias have been observed in the *C3HeB/Fe* mice which were routinely kept under observation until they were 14 months old.

The nucleic acids were extracted from the spleen, lymph node and thymus cells of leukaemic *AKR* and normal *C3HeB* mice by a modification of Kirby's cold phenol *p*-aminosalicylic acid method described previously[4]. The preparations contained both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) in concentrations of 500–1,000 μg/ml. of DNA and 100–200 μg/ml. of RNA.

In the first experiment, suspensions of adult thymus cells, thymus cells of 5–6 day-old mice, or 10–19 day embryos were prepared by trypsinization from mice of the *C3HeB/Fe* strain. The cells were suspended in 5–10 c.c. of medium 199 or Eagle's medium. They were placed in 15 ml. culture tubes or 60 mm Petri dishes. In some of the initial experiments horse serum or foetal calf serum was added to a final concentration of 10 per cent. Serum was not utilized in later experiments because of the possibility of its nucleases inactivating the added nucleic acid. 0·5 ml. of nucleic acid was added to these cell suspensions at zero time. The experimental cells were incubated in nucleic acid extracted from leukaemic tissues of *AKR* mice and the control cells were incubated in nucleic acid from normal lymphoid tissue of *C3HeB* mice. The incubation time was 5–24 h at 37° in an incubator with 5 per cent carbon dioxide in air. The cell suspensions were agitated from time to time. At the end of the incubation period the cells were injected intravenously and, in a few instances, intraperitoneally into new-born *C3HeB/Fe* mice. In each instance approximately 1–2 million cells were inoculated. Eosin tests for viability (utilizing the principle that viable cells do not stain with dilute solutions of eosin) showed that more than 90 per cent of the cells were viable after 4–5 h of incubation and 50 per cent of the viable after 18–24 h. The animals were killed when 14 months old and only animals living longer than 6 months, the usual lowest age of onset of spontaneous *AKR* leukaemia, were included in the experiment.

The second experiment was of somewhat different design. The recipient animals and all the tissues used were from *AKR* strain mice. The test animals were thymectomized using 'Nembutal' and 'Fluothane' anaesthesia when 5–6 weeks old, and a week later were grafted subcutaneously with both thymuses from 1–3-day-old *AKR* mice. The incision for grafting was made in the left groin and the grafts were inserted by a subcutaneous tunnel on to the left anterior chest wall. The thymic lobes were placed in Tyrode's solution with 100 u./c.c. of penicillin and streptomycin prior to grafting. Ether anaesthesia was used for the grafting procedures. All the host animals were females; the donor thymuses were from both sexes as were the incubated cells.

When mice grafted with neonatal thymus were killed at 2-day intervals, it was found that the thymus underwent an initial regression with disappearance of cortical lymphocytes. There was a return of the lymphocytic population at 11–14 days of age. After 19 days the graft resembled normal thymus. On the tenth day after thymus grafting, a time when the graft had been shown to be reconstituting its lymphocyte population, the thymectomized and grafted mice were inoculated intravenously with normal thymus cells from 3-week-old *AKR* mice. The 0·25 ml. inoculum consisted of 1–8 million cells; one group of mice was given cells which had been incubated in hypertonic buffer containing leukaemic cell nucleic acid and the second group of animals received cells which were incubated in hypertonic buffer without nucleic acid. The method of incubation followed closely that of Weil[3], and was as follows: the cells were teased from the whole organ in Tyrode's solution. They were gently centrifuged and the supernatant decanted. Hypertonic sodium chloride (0·55 M) in 0·03 M *tris* buffer at *p*H 7·8 was added to the cells which were then centrifuged at a low speed. The supernatant was decanted and 1 ml. of the nucleic acid solution (1 : 10 dilution from our original preparation) was added. The cells were mixed with the nucleic acid and incubated 15 min in a water bath at 37°. At the end of incubation 9 ml. of Tyrode's solution was added; the solution was then mixed, centrifuged, and re-suspended in 2–3 ml. of Tyrode's solution for inoculation. The hypertonic treatment increased the eosin permeability from 5–10 per cent to as much as 100 per cent in some instances. Because the hypertonic treatment in the first experiment resulted in an increased number of eosin-permeable cells, all succeeding cell suspensions contained mixtures of cells incubated in both hypertonic and isotonic medium. Whether eosin permeability meant death in all these instances is questionable, for when the hypertonic incubated cell suspensions were placed in the refrigerator for 5–10 min the number of eosin permeable cells decreased.

Incubation of *C3H* Cells with *AKR* Leukaemic Cell Nucleic Acid–First Experiment

In this experiment 59 animals received cells incubated with *AKR* leukaemic cell nucleic acid. One of these animals developed a lymphoma when 10 months old. This animal had received 10^6 cells, 90 per cent eosin-negative, by the intravenous route at about 24 h after birth. These cells had been incubated for 5 h in the leukaemic nucleic acid prior to inoculation. The suspending medium was Eagle's with 10 per cent horse serum. The lymphoma was characterized by massive enlargement of peripheral nodes, spleen, and liver. There was no enlargement of the thymus or mesenteric nodes. Microscopically the tumour was a reticulum cell sarcoma. There were 56 animals receiving cells incubated in normal *C3H* lymphoid cell DNA. No lymphomas were seen in this group.

Incubation of Normal *AKR* Cells in Leukaemic Cell Nucleic Acid in Hypertonic Medium–Second Experiment

The design of this experiment was to determine if nucleic acid from leukaemic cells could effect a leukaemic transformation of normal isogenic thymic cells. It was assumed that if this occurred it would happen during, or shortly after, the time of incubation and the transformed leukaemic cells would produce disease as does a leukaemic cell transfer, that is, within 2 months, and that the regenerating thymus would provide a suitable environment for these cells. Leukaemic transformation,

however, did not occur. All the experimental animals were completely normal 2 months after the cell inoculations.

Observation of the animals up to the age of 12 months revealed some interesting and unexpected findings. The normal spontaneous incidence of leukaemia was strikingly reduced in the experimental mice. Fourteen mice were thymectomized, isografted with neonatal thymus, and inoculated 10 days later with a 3-week-old thymus cell suspension which had been incubated in leukaemic nucleic acid in a hypertonic medium. Four of these animals (28 per cent) developed lymphocytic leukaemia when 9–12 months old. The disease was morphologically identical to the spontaneous *AKR* disease and involved all the lymphoid organs. In three animals the graft was also involved and in the fourth it was completely normal. The remaining ten mice in this group were killed when 12 months old and no evidence of lymphoma was found. The grafts were viable and normal in appearance and were 5–10 mm in diameter. A second group of thirty mice were prepared in the same way but given a mixture of cells incubated with nucleic acid in hypertonic and isotonic medium. Three of these animals (10 per cent) developed typical lymphocytic leukaemia involving the graft as well as other organs. The remaining twenty-seven mice when killed at 12 months of age were completely normal with normal-appearing thymus grafts. The animals in both these groups had complete thymectomies.

A third group of mice were also thymectomized, and grafted with neonatal thymus. Ten days later these animals received thymus cells from 3-week-old animals incubated in hypertonic and isotonic medium without nucleic acid. None of these animals developed lymphoma and all were completely normal when killed at 12 months of age. The thymus grafts were all fully viable, and of normal morphology, and the thymectomies were complete.

Thirty-four intact *AKR* control mice were raised at the same time and under the same conditions as the experimental mice. Twenty-four, or 70 per cent, of them developed thymic lymphomata at a mean age of 11·2 months (range 6–12 months). The animals were observed until 12 months of age. These results are summarized in Table 1.

Table 1. Incidence of Lymphoma in Thymectomized-grafted *AKR* Mice given 3-week-old Isogeneic Thymus Cells 10 Days Post-grafting *

Treatment of cells	No. of mice	No. of lymphoma	Age of onset in months
Incubated with nucleic acid in hypertonic medium	14	4(28%)	9, 10, 12, 12
Incubated with nucleic acid in hypertonic and isotonic medium	30	3(10%)	9, 11, 11,
Incubated in hypertonic and isotonic medium	31	0	
Intact controls	34	24(70%)	6–12 mean 11·2

* All animals either died of lymphoma or were killed when 12 months old.

An analysis of the type of inoculum given these animals is presented in Table 2. As already mentioned, a portion of the cells was mixed with dilute solutions of eosin just before inoculation and cells staining with this dye were considered not to be viable. In the first group of experiments (inocula 1 and 2) the cells were all stained with eosin after the hypertonic treatment, hence in the subsequent inocula thymus cells incubated in DNA in isotonic solution were added to provide some viable cells. Two of six and two of eight mice developed late lymphomata after the inocula, which did not contain any 'viable' cells by the eosin test. Two of thirteen animals developed the disease when given a mixture of 'viable' and 'non-viable' cells, incubated in leukaemic DNA. In the 31 mice receiving inocula 5, 6 and 7, which did not contain nucleic acid but consisted of varying cell doses and 'viabilities', no lymphomata were seen.

These investigations show that *in vitro* incubation of normal isogenic thymus cells with nucleic acid extracted from leukaemic tissues of mice with spontaneous disease does not result in a direct leukaemic transformation of the cell or in a transformation to a precursor cell of leukaemia. If direct transformation had occurred in both of these studies one would have expected leukaemia development within 2–3 months after inoculation of the 'transformed' cells. If the nucleic acid incubation had effected a change to a precursor cell in the *C3HeB/Fe* mice in the first experiment the development of late leukaemias occurring after 6 months of age might have been seen. The one reticulum cell sarcoma developing is of interest since no others have been seen in the *C3HeB* mice, but certainly one cannot make any statements relating it to the neonatal inoculation of nucleic acid-treated cells.

The hypertonic treatment of the cells utilized in the second experiment has been shown by Weil[3] to result in effective *in vitro* incorporation into cells of DNA from polyoma virus. Therefore we can assume that the NA entered these cells but did not have any direct biological effect as measured by the studies utilized.

The suppression of the incidence of leukaemia in the *AKR* mice in the second study is of considerable interest. These animals were thymectomized, isografted, and then inoculated with normal thymus cells treated in a hypertonic medium with and without nucleic acid. The results show a general suppression of leukaemogenesis in the nucleic acid and control groups, therefore it is unlikely that the nucleic acid incubation was responsible for the lack of development of leukaemia. The leukaemias seen in the animals receiving cells treated with nucleic acid may well have been due to the lack of viable cells in the inoculum. This point will be discussed later.

It is an established observation that thymectomy results in a striking decrease in the incidence of lymphocytic leukaemia in *AKR* strain mice[5]. Subcutaneous isografts of 4-week-old thymus into thymectomized *C58* mice, another strain with a high natural leukaemia incidence which is reduced by thymectomy, have been shown to restore the incidence to that of intact controls[6]. Such studies on *AKR* mice have not been reported, but in experiments utilizing intact F_1 hybrid mice where the dam was of the *AKR* strain, subcutaneous grafts of 1-week-old *AKR* thymus into these $(AKR \times C57BL)F_1$ mice resulted in an incidence of lymphoid leukaemia of 20 per cent compared with 9 per cent in the controls[7]. In $(C3H \times AKR)F_1$ hybrid mice, not thymectomized but grafted with 4–5-week-old *AKR* thymus, the lymphoid leukaemia incidence was 60·9 per cent as compared with 27·7 per cent in the control animals[8]. These observations indicate that the presence of an *AKR* thymus promotes leukaemogenesis and strongly suggest that subcutaneous grafts of this organ should restore the high leukaemia incidence in thymectomized *AKR* mice. In our experiments, however, this was not the case. Isogenic 1–3-day-old thymus was used for grafting the thymectomized hosts, while in the aforementioned reports thymus grafts from older mice were utilized. However, the histological changes observed postgrafting in our studies were like those observed by Law[8] for subcutaneous grafts of thymuses from 4–5-week-old *AKR* donors as well as like these described by Dukor *et al.*[9] occurring in the subcutaneous isografts of new-born thymus in thymectomized hosts. Miller[10] also has shown that in virus-inoculated mice, in which thymectomy abolishes leukaemia development, grafts of neonatal thymus in 4–5-week-old recipients result in the same high percentage of leukaemias as seen in virus-inoculated, intact controls. These observations make it unlikely that the age of the thymus graft played an important part here.

Another possibility might be that the grafting postponed the age of onset of leukaemia and that, if the animals had been observed longer, a high incidence might have been seen. There is, however, no support for this in the experi-

ments in which *AKR* (ref. 8) and *C58* (ref. 6) grafts were used and in which the time of onset of leukaemia occurred earlier than, or at the same time as, that of the controls.

An explanation of the inhibition of leukaemogenesis seen in the isografted cell-inoculated mice might be that an altered pattern of regeneration of the thymus graft was promoted by the inoculation of viable cells on the tenth day after grafting and that this resulted in suppression of leukaemia development. The phenomenon of altered regeneration of the thymus has been observed in irradiated *C57BL* mice given intravenous inoculations of viable bone marrow cells[11]. The animals treated in this manner had a much lower incidence of leukaemia than did irradiated mice of the same strain[12]. It was also found to be true in the case of subcutaneous grafts of thymus in thymectomized, irradiated mice[13], that is, the thymectomized, irradiated *C57BL* mouse when grafted with isogenic thymus subcutaneously has a considerably higher leukaemia incidence than the thymectomized, irradiated and thymus isografted mouse that has also been given intravenous doses of bone marrow cells from a single femur of an isogenic animal. Therefore, the reduction of leukaemia incidence is the result of an altered and probably more rapid regeneration of the thymus presumably promoted by the prompt regeneration of the irradiated haematopoietic tissue by stem cells in the marrow inoculum.

Table 2. Cell Viability as determined by Permeability to Eosin in the Various Inocula

Treatment of cells	Inocula	No. of cells inoculated	Percentage of unstained cells*	Lymphoma/Mice inoculated
Incubated with nucleic acid in hypertonic medium	1	6×10^6 on successive days	Zero	2/6
		2×10^6 on successive days	Zero	
			Zero	
	2	3×10^6	Zero	2/8
Incubated with nucleic acid in hypertonic and isotonic medium	3	2×10^6	75%	2/13
	4	1×10^6	35%	1/17
Incubated in hypertonic and isotonic medium	5	$4{\cdot}7\times10^6$	75%	0/14
	6	8×10^6	80%	0/9
	7	$2{\cdot}7\times10^6$	20%	0/8

* Cells placed in a dilute solution of eosin and counted under the microscope prior to inoculation.

In the experiments reported here, as is shown in Table 2, the leukaemia incidence was lowest in the animals receiving the inocula with the greatest numbers of viable cells, on the tenth day after grafting. Dukor *et al.*[9] have shown that the regeneration of the thymus after subcutaneous grafting was accomplished initially by donor cells, but at the end of the second week the donor cells began to be replaced by host cells. Complete host cell repopulation was accomplished by day 21. Inocula of additional viable thymus cells in our experiments, then, were given at the time when regeneration of the original graft was nearly complete and when the host cells were beginning to repopulate it. This could have resulted in an altered pattern of regeneration of the thymus, one not compatible with leukaemogenesis. These observations suggest that the sequence of events occurring in the thymus under these experimental conditions differ in some important way from those occurring naturally in the *AKR* thymus.

Nucleic acids extracted from leukaemic tissues of *AKR* mice were incubated *in vitro* with cells of mice of a low incidence leukaemia strain (*C3HeB/Fe*) and inoculated intravenously into new-born mice of the same strain. Similar nucleic acid preparations were incubated with normal *AKR* thymus cells *in vitro* in a hypertonic medium. These cells were then inoculated intravenously into thymectomized adult *AKR* mice with regenerating thymic isografts. No early leukaemias were seen in either group, indicating that direct nucleic acid-mediated leukaemic transformation did not occur. The absence of late leukaemias in the *C3HeB* mice also indicated that there was no transformation to a precursor cell of leukaemia when the cells were incubated with leukaemic cell nucleic acid.

The marked depression of leukaemia incidence observed in thymectomized, isografted *AKR* mice inoculated with *AKR* thymus cells could have been due to a more prompt thymic graft regeneration resulting from the administration of viable thymus cells.

These studies were supported by a contract between the U.S. Atomic Energy Commission and the University of California at Los Angeles.

MICRO-AEROBIC CAPABILITIES IN LAND PLANTS: OBSERVATIONS ON SURVIVAL AND GROWTH OF PLANTS SUBMERGED IN FRESH AND SALINE WATERS

By Dr S. M. SIEGEL, C. GIUMARRO and O. W. DALY
Union Carbide Research Institute, Tarrytown, New York

INVESTIGATIONS in this laboratory have shown that seed germination and seedling growth of many common vascular land plants occur with little or no oxygen[1–4]. In a number of cases, the rates of germination or seedling growth at reduced oxygen pressures have exceeded the rates in air. In the course of this investigation, it was recognized that the vigour of micro-aerobic plant growth may reflect a similar micro-environment of the seed and pre-emergent seedling in Nature. Air compositions beneath the soil surface, for example, may be radically different in their partial pressures of oxygen and carbon dioxide (P_{O_2}, P_{CO_2}) and in respect to the presence of hydrogen and methane from those above the soil surface[5,6]. The extent of such differences will depend on the structure, water table, drainage, and organic matter of the soil, and on the microflora and fauna present.

Among the factors which determine the P_{O_2} of the soil, the presence of water is of major importance. P_{O_2} will vary from that in relatively more aerobic, well-drained soil through heavier, poorly drained substrata,

muck, marsh and swamp-lands, to free-standing fresh, brackish, or sea-waters. Even shallow waters can be anaerobic or nearly so. Thus, Wetzel[7] showed that 5 cm below the surface of a pond which he investigated, the oxygen level at no time exceeded 0·21 vol. per cent and most of the year ranged from 0·0 to 0·01 vol. per cent. The bottom mud, only 15 cm in depth, was always anaerobic and rich in hydrogen sulphide.

Vascular plants native to aquatic habitats are usually treated as a group apart which requires a buoyant medium, perhaps as a consequence of loss in lignifying capacity. However, plants such as *Elodea* and *Salvinia* can live in such water, which serves primarily as a substratum and the atmosphere of importance is the gas phase which they contact. Others, *Typha* and *Alisma*, for example, may be rooted in anaerobic bottom sediments, extend through a micro-aerobic liquid phase, and emerge into the gaseous atmosphere[8–11].

Within the context of the foregoing discussion, the existence of micro-aerobic capabilities among vascular plants native to mesic or xeric conditions raises questions about the commonly held theories relating excess water and poor aeration to plant damage[12] and suggests that even submergence should not be a barrier to the survival and distribution of many species.

General observations on germination and growth. Aerated water at 20°–30° C, and 1 atm. pressure, saturates at about 0·8 vol. per cent oxygen; oxygenated water contains approximately 4 vol. per cent. In order to facilitate comparisons, we have generally treated submerged systems as analogues of plants in air. That is, the ambient fluid phase, whether liquid or gaseous, is the 'atmosphere' into which the plant, resting on a supporting surface, extends.

Submergence trials were generally carried out in 6-l. battery jars approximately 30 cm in depth. Aeration or oxygenation was carried out using sintered glass tubes. Dissolved oxygen was determined by a Beckman immersible oxygen electrode. No other special conditions or techniques were used.

Determinations of nitrogen, phosphorus, sulphur and ash were carried out by Micro-Tech Laboratories, Skokie, Illinois; halogen analyses were run by Schwarzkopf Laboratories, Long Island City, New York. Other analyses were carried out in this laboratory using routine procedures.

Preliminary experiments showed that several species germinated well when submerged in aerated water (oxygen about 0·8 vol. per cent), but in stagnant water (oxygen < 0·1 vol. per cent) only rice showed appreciable activity (Table 1). Of the species tested, only the beet required an oxygen-saturated medium. Cucumber and rye germinate well in a gaseous anaerobic medium, but not at all when submerged[3,4]. Failure of gas phase anaerobes to perform when submerged could be in part a result of accumulation of bicarbonate (carbon dioxide) under stagnant conditions.

Table 1. Germination Percentage of Submerged Seeds after 6 Days

Species	Oxygen vol. per cent		
	< 0·1	0·8	4
Beet (*Beta vulgaris*)	0	2	41
Cucumber (*Cucumis sativus*)	8	100	96
Marigold (*Tagetes* sp.)	0	56	100
Rye (*Secale cereale*)	0	100	100
Rice (*Oryza sativa*)	90	89	83
Barley (*Hordeum vulgare*)	0	66	—
Pole bean (*Phaseolus vulgaris*)	0	72	—
Lettuce (*Lactuca sativa*)	0	68	—

It appears from our limited number of experiments that the ambient medium *per se* is a factor in anaerobiosis, that a low volume percentage of oxygen in water is sufficient for many submerged species to grow, and that rice is an example of a true sub-aquatic anaerobe.

A comparison of growth in gaseous and aqueous 'atmospheres' was made on rye seedlings (Table 2). After 10 days in argon (oxygen < 0·005 per cent) the seedlings produced 10–20 mm shoots, some with primary leaves emerging from the coleoptiles. A gas-phase optimum oxygen level which was sub-atmospheric was evident. In the aqueous phase an optimum was also evident, but at a decidedly lower oxygen level. Clearly the 'operational' range of oxygen levels for the growth of rye is lowered and narrowed quite markedly in aqueous as contrasted with gaseous systems.

Table 2. Comparison of Rye grown in Approximately Equivalent Volume Percentages of Oxygen in Air and Water

Oxygen concentration Vol. per cent	Shoot height after 10 days (mm) 'Atmosphere'	
	Gaseous	Aqueous
< 0·1	15	< 1
0·8 (air-saturated water)	58	75
4·0 (oxygen-saturated water)	136	38
20·9 (air)	90	—

Root initiation in *Coleus blumei* cuttings has been compared. Air controls were set up with 4–6 cm plants extending out of 2 cm of water, whereas submerged whole plants were beneath approximately 20 cm of aerated or stagnant water. By the tenth day, 10–12 roots per plant were present in controls, 5–7 in aerated water, and none in stagnant water.

Other experiments have shown shoot growth in bulbs of *Narcissus* but, unexpectedly, comparable responses were observed in submerged specimens whether aerated or not.

Constitution of air-grown and submerged rye. Winter rye was selected for extended comparative investigations of the submerged state. The selection of rye was prompted by its tolerance to unusual or exotic environmental conditions[13].

About one hundred plants each of 10-day-old air-grown and aerated underwater-grown rye were subdivided for microscopic and chemical analyses. The microscopic examination was carried out using fresh free-hand sections of leaves (Table 3). This revealed that both epidermal and internal (mesophyll) cells were larger in the submerged group; that a distinct cuticle was not noticeable, if present at all; and that intercellular spaces were not noticeably different in magnitude, but submerged plants had somewhat reduced numbers of chloroplasts per cell. The enlarged state of leaf cells suggested a higher degree of succulence, or a 'waterlogged' condition. When samples of submarine rye were transplanted into ordinary conditions in air, they showed a pronounced tendency to collapse within a few days, and generally lacked the mechanical integrity of air-grown plants. This change was not, however, a result of 'waterlogging', as their dry matter content shows (Table 4).

Table 3. Overall Growth and Cellular Comparisons: Air versus Aerated Underwater-grown Rye at 10 Days

Measurement	*a* Air-grown	*b* Submerged	*b*/*a* (per cent)
Shoot height (mm)	90 ± 12	75 ± 15	83
Root height (mm)	72 ± 10	100 ± 17	139
Epidermal cell diam. (μ			
Upper	29·8 ± 1·2	50·5 ± 10·0	169
Lower	26·4 ± 1·5	39·0 ± 2·8	148
Epidermal hair cell			
Length (μ)	109·6 ± 15·1	136·0 ± 14·7	124
Width (μ at mid-point)	9·5 ± 1·0	10·4 ± 1·2	109
Nucleus (μ diam.)	5·4 ± 0·5	7·4 ± 0·8	137
Mesophyll cell diam. (μ	27·3 ± 2·0	33·4 ± 3·6	122
Chloroplast (No./cell)	29·2 ± 3·0	22·4 ± 2·9	77

We found that submerged plants were richer in organic nitrogen, phosphorus and sulphur. The biochemical significance of this difference is not yet known. Increased protein nitrogen has, however, been noted previously in bean plants grown in 5 per cent oxygen[2]. In contrast to such differences, the linear rates of growth of controls and submerged plants are comparable. The analyses of organic materials have been limited to the components listed in Table 5. The chlorophyll content is slightly reduced in submerged plants, but less so than the number

Table 4. Analytical Comparisons: Dry Matter and Elementary Constituents in Air versus Aerated Underwater Rye After 10 Days' Growth

Analysis	*a* Air-grown	*b* Submerged	*b*/*a* (per cent)
Dry weight (per cent)			
Shoot	8·5	7·8	92
Root	7·8	8·5	109
Total N (mg/g dry wt.)			
Shoot	47·2	58·9	125
Root	22·2	33·8	152
Organic P (mg/g dry wt.)			
Shoot	5·4	6·9	128
Root	4·6	6·8	148
Organic S (mg/g dry wt.)			
Shoot	4·2	5·5	131
Root	1·3	2·7	200
Ash (mg/g dry wt.)			
Shoot	60·5	113·8	187
Root	275·3	173·2	63

Table 5. Analytical Comparisons: Organic Components in Air versus Aerated Underwater-grown Rye at 10 Days

Analysis	*a* Air-grown	*b* Submerged	*b*/*a* (per cent)
Chlorophylls (mg/g dry wt.)			
a	5·0	4·5	90
b	2·4	2·2	92
	Total 7·4	6·7	91
Cell wall (mg/g dry wt.)			
Shoot			
Cellulose	365	270	70
Non-cellulosic polysaccharides	200	154	77
Root			
Cellulose	406	510	123
Non-cellulosic polysaccharides	167	129	77
Glucose (mg/g dry wt.)			
Shoot	58·1	71·0	122
Root	40·0	17·7	44

of chloroplasts per cell. The chlorophyll *a* : *b* ratio is unchanged.

Microscopic examination also suggests that the cell walls of air and submerged groups differ. In the shoot, only a slight reduction in cellulosic and non-cellulosic constituents is evident, but in the root, there is a shift to a higher proportion of cellulose relative to total dry matter and total cell wall. The glucose content of the submerged shoot is also increased (perhaps a reflexion of reduced wall synthesis) but is quite reduced in the root, perhaps as a consequence of increased cellulose synthesis.

Tissue spot tests (Table 6) show that submerged tissues are poorer in catalase and richer in peroxidase than those grown in air, a response also found in comparing beans grown in air and 5 per cent oxygen[2].

Table 6. Histochemical 'Spot' Tests on Whole Air and Aerated Underwater-grown Rye Seedlings

Reagents	Test	Response: Air-grown	Response: Underwater-grown
M/10 hydrogen peroxide	Catalase	+ + +	+
M/100 hydrogen peroxide M/100 pyrogallol	Peroxidase	+	+ + +
Saturated ammonium molybdate	*ortho*-diphenols	+)	–
1 per cent phloroglucinol in hydrochloric acid			
(*a*) In fresh tissue	Lignin + precursors	+	+
(*b*) In alcohol-extracted tissue	Lignin (polymer only)	+	–
1 per cent glucose-1-phosphate + potassium tri-iodide	Phosphorylase	+	+
Potassium tri-iodide	Starch	+	–

Fresh tissues, especially roots, show a positive lignin test, but the phloroglucinol colour reaction is also given by coniferaldehyde and related precursors (monomers)[8]. The precursors are soluble in alcohol and in water, and after extraction, submerged tissues are negative, but the solution is phloroglucinol-positive, indicating the presence of unpolymerized precursor. Ultra-violet spectra of extracts made with cold 4 per cent sodium hydroxide confirm that there is more soluble phenol in submerged roots. Again, the response of submerged rye resembles that of other species grown in sub-atmospheric oxygen levels[2].

Roots of both groups can convert glucose-1-phosphate into amylose (phosphorylase-positive), but the submerged roots are devoid of starch.

Preliminary experiments also showed that rye seedlings grow nearly as well in aerated 1–3 per cent sodium chloride solution as in distilled water (Table 7). Increased salinity is partially reflected in altered fresh weight, and reduction in non-halogen-containing dry matter. Work in progress also shows that solutions of 1 per cent sodium bromide and sodium iodide can support reasonably good seedling growth. In addition to accumulation of appreciable water-soluble halide ion, these plants contained up to several hundred p.p.m. of water-insoluble—presumably organically combined—chlorine, bromine or iodine. Plants have also been grown submerged in solutions of calcium, magnesium and potassium salts.

Table 7. Effect of Sodium Chloride on Growth and Dry Matter in Submerged Aerated Rye

Measurement (10 days)	Sodium chloride (weight per cent) 0	1	3
Length (mm)			
Shoot	97	110	75
Root	80	71	64
Fresh weight (mg/plant)	110	170	140
Dry matter (mg/g fresh wt.)			
Organic	135	109	105
Inorganic (–chlorine)	18·8	13·8	15·5
Chloride	0·2	4·2	5·5

The results of these and related experiments will be detailed separately when completed.

Survival of air-grown plants under water. So far, submerged growth initiated by way of seed germination has been considered. The tolerance of air-grown and air-adapted plants might conceivably fall below that of seedlings actually grown under these novel conditions. Although a direct comparison has not been made, several species have been tested for survival in aerated water (Table 8). In order to heighten the contrast, a number of zerophytes were included, and two of these, both *Euphorbia* species, showed the highest tolerance. After 9 months

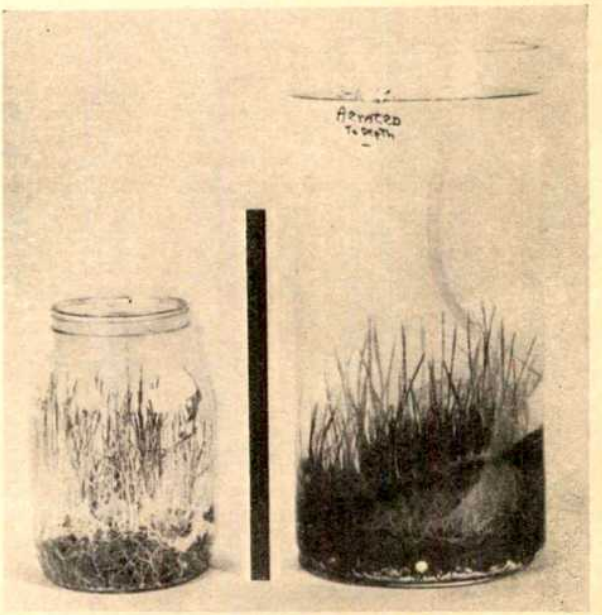

Fig. 1. Comparison of rye grown from seed in air (left) and under aerated water after 10 days

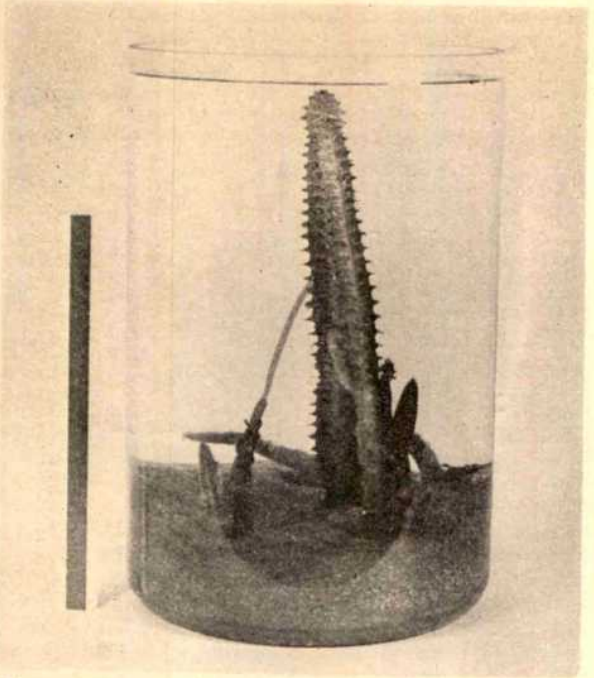

Fig. 2. *Euphorbia hermentiana* after 2 months' submergence in aerated water

of continuous submergence, *E. hermentiana* (Fig. 2) was still essentially unchanged except for the appearance of new leaves as much as 2 cm in length above the water line and many new roots varying from 4 to 40 cm in length within the sand substratum. The same species can also produce leaves, but no roots, when allowed to remain unplanted and unwatered under ordinary laboratory conditions.

Table 8. Tolerance of Selected Plants to Submergence in Aerated Water

Species	Condition after various submergence periods (Months)		
	1	3	9
Euphorbia hermentiana	+*	+	+‡
Euphorbia xylophylloides	+	+	−
Cereus peruvianus	+	−	−
Senecio gregori	+	−	−
Cotyledon sp.	+	−	−
Gasteria hybrida	+	−	−
Coleus blumei	−†	−	−
Hedera helix	−	−	−

* +, Normal turgor, colour; no sign of necrosis; no surface microbial growth.
−, Colour changes, necrosis, and microbial growth marked.
† Root growth still evident after 1 month.
‡ Both root and leaf growth evident.

It is of interest that *E. hermentiana* tolerates gas phase anoxia well, and shows appreciable viability for periods of up to 2 months in atmospheres rich in normally noxious gases such as ammonia[14].

For comparative purposes, the tolerance to submergence of several invertebrates was tested. The earthworm, *Lumbricus terrestris*, remains continuously active in aerated distilled water for at least one week, dies within hours under stagnant conditions, and survives in 1–3 per cent sodium chloride solutions for 3 days. The millipede, *Iulius*, which is relatively tolerant of low oxygen levels in the gas phase dies[15] in 1·5 days in aerated water, but remains active for more than 3 days in oxygenated water. The beetle, *Passalus* sp., and the spider, *Miranda aurantia*, die within hours in oxygenated water.

Von Brand reports species of nematodes, gastrotrichs, rotifers and oligochaetes capable of surviving periods of 2–4 months under anaerobic or near-anaerobic conditions[16]. In contrast, other obligate water forms, the molluscs and echinoderms, show little tolerance to anaerobic or micro-aerobic conditions, surviving for hours generally, rarely for several days. Crustaceans show somewhat better performance, as do aquatic insect larvae.

The biological significance of submergence studies. In some respects, the experiments described and discussed above are highly artificial, and perhaps somewhat surrealistic, in so far as they apparently place ordinary land plants and 'ordinary' (simulated) aquatic or marine conditions together in unnatural or unreal combination. This is not true for rice, of course, but applies to rye, *Euphorbia* and most other forms used. This criticism is misdirected, to some extent, since many mesic and even xeric environments are subject to periodic flooding or submergence by fresh or brackish waters. There is thus an autecological aspect to these experiments, inasmuch as they offer an explanation for the tolerance which some species show to submergence, even in saline waters.

Further ecological significance may be derived from a comparison of the micro-aerobic capabilities of specified land forms and their actual distribution in poorly aerated soils or shallow standing waters. *Typha*, as noted earlier, fits such considerations well, as does rice, but rye and *Euphorbia* do not occur naturally in environments which they could apparently tolerate. This suggests that such forms are not excluded from water-logged soils or other watery environments *per se*. The analysis of the factors responsible for their distribution is beyond the scope of this article, whereas the elimination of an often-invoked factor—soil oxygen supply—is.

Beyond the ecological and micro-ecological areas, this investigation has a bearing on the general fields of stress physiology and exo-biology. In order to define, at the various levels of bio-organization, the extreme parameters of survival, one not only has licence, but is required, to venture into organism-environment combinations that have no close natural counterpart. In the present case, plants normally associated with a two-part system—supporting substratum plus gaseous atmosphere—are placed in an analogous situation in a liquid 'atmosphere'. This work emphasizes further that a hardy species will show high performance under a multiplicity of stress conditions. That is, stress tolerance is not necessarily a matter of specific 'fit' into or selection for a particular condition, but may also be a reflexion of a general state of plasticity of the genome. Again, both rye and *Euphorbia* qualify as competent multi-stress forms whereas a species such as *Coleus* has low tolerance toward extremes of atmosphere, temperature, and their combinations.

From an experimental physiological-biochemical point of view, the plant in its submerged environment can be treated uniquely in terms of growth regulation and metabolism. A new mode of application to the 'aerial' plant of hormones, nutrients and metabolites is now possible. Translocation–transpiration–stomatal relations and cuticular exchange processes must be totally altered.

Evidence suggesting that the 'norms' of regulatory processes are changed with modified Po_2 (ref. 17) has been extended with observations on geotropism. Although the coleoptile is invariably orientated in an 'upward' direction, many roots are randomly disposed relative to gravity when rye is germinated under water. In an extreme case, a 100-mm negatively geotropic shoot was accompanied by several positively geotropic roots of 5–20 mm and one negatively geotropic root more than 250 mm in length. Cucumber seedlings showed even more striking disturbances, including geotropic reversals.

The metabolic effects of submergence are clearly indicated by the changes in chemical composition in rye, many being reminiscent of the effects of growth in a micro-aerobic gas phase.

The cultivation of land forms under water is thus a reasonable extension of and useful addition to previous environmental approaches centred about the gas phase.

VERTEBRATE EPIDERMAL MELANIN UNIT

By MAC E. HADLEY and WALTER C. QUEVEDO, jun.
Division of Biological and Medical Sciences, Brown University, Providence, Rhode Island

MELANIN pigmentation of mammalian epidermis involves the formation of melanin granules within melanocytes and their transfer to malpighian (receptor) cells. The total intensity of epidermal pigmentation is related to the qualitative and quantitative attributes of melanin granules within both types of cells. The close integration of melanocytes and malpighian cells in pigmentation of mammalian skin has been stressed in the concept of the 'epidermal melanin unit' developed by Fitzpatrick and Breathnach[1]. The 'epidermal melanin unit' has been defined as a melanocyte with an associated pool of malpighian cells, the size of which may be variable. In this view, factors which influence any component in the 'epidermal melanin unit' might be expected to modify the function of the entire system. For example, ultra-violet light may act to stimulate melanogenesis, not by a direct action on melanocytes, but rather, indirectly, by inducing proliferation of malpighian cells, thereby providing more vehicles for melanin transport[1].

Genetic mechanisms appear to influence the size of mammalian 'epidermal melanin units' by their effects on melanocyte morphology. Dilute black (*ddBB*) murine melanocytes have shorter melanotic dendritic processes than more highly branched non-dilute (*DDBB*) melanocytes. Owing to the reduction in dendritic processes, the dilute melanocytes appear to maintain contact with fewer malpighian cells and accordingly have fewer vehicles available for melanin transport than comparable non-dilute melanocytes[2,3].

The 'epidermal melanin units' of mammals may overlap, with two or more melanocytes sharing some malpighian cells in common, or they may be discrete with no apparent overlap in their populations of epidermal cells. The overlapping of 'epidermal melanin units' is determined by the morphology of melanocytes and their population density.

As yet, there has been no attempt to extend the concept of the 'epidermal melanin unit' to other classes of vertebrates. Based on the definition provided by Fitzpatrick and Breathnach, it would appear that such units not only are present in mammalian skin but also exist in the skin of certain reptiles[4] and amphibians[5]. Their general occurrence elsewhere among vertebrates awaits clarification. This communication documents the existence of 'epidermal melanin units' among amphibians and stresses the importance of the comparative approach to an understanding of epidermal cell–melanocyte interactions in pigmentation of the skin.

Although there are numerous conflicting reports on the part played by epidermal melanocytes in colour changes in amphibians, our investigations indicate that under appropriate conditions the responses of the epidermal melanocytes of certain amphibians are entirely predictable[6]. This information is derived largely from investigations on the leopard frog, *Rana pipiens*, but similar investigations on several other species of amphibians (for example, *Xenopus laevis* and *Diemyctylus viridescens*) have yielded comparable results.

When adult *Rana pipiens* are placed on a white background and illuminated from above, there is an aggregation of melanin granules within epidermal melanocytes; this is in contrast to the dispersion of melanin granules found in the epidermal melanocytes of frogs placed on a black background under similar lighting conditions. *In vitro* investigations also indicate that the distribution of melanin granules within epidermal melanocytes is influenced by some of the agents (for example, caffeine, commercial ACTH, 'Pituitrin') with known action on pigment mobilization within dermal melanophores[7]. However, melatonin is a noteworthy exception; though effective in causing melanin granule aggregation in the dermal melanophores at extremely low concentrations it has no demonstrable influence on the epidermal melanocytes even at extremely high concentrations.

The epidermal melanocytes of frogs possess the dual capacity to synthesize melanin granules for transport by epidermal cells and to mobilize melanin granules intracellularly in a manner adaptive to the colour of the background. The population of epidermal cells actively receiving melanin granules from an epidermal melanocyte is determined by the extent to which melanin granules are distributed throughout its highly branched processes. In animals adapted to a neutral background, or as captured in the field, fewer epidermal cells receive melanin granules from a given epidermal melanocyte than in animals adapted to a black background. In contrast, the melanocytes of frogs adapted to a white background release less melanin and the newly released melanin granules are frequently restricted to those epidermal cells immediately adjacent to the melanocyte perikaryon which contains the aggregated melanin granules. In frogs adapted to a neutral background, regions of the epidermis where the density of epidermal melanocytes is low are characterized by many 'epidermal melanin units' which are discrete, having little or no functional overlap. Each melanocyte may possess its own distinctive constellation of epidermal cells for pigment transport; a halo of non-pigmented epidermis often separates the individual units (Fig. 1*A*).

When frogs are adapted to a black background for an extended period of time, functional overlap of 'epidermal melanin units' is observed in regions of the epidermis previously characterized by discrete 'epidermal melanin units' (Fig. 1*B*). This results when melanin granules are dispersed throughout the more distal regions of the branched processes of the melanocytes and consequently are distributed to a greater number of epidermal cells. This overlapping of functional units results in the seeding of previously non-pigmented epidermal cells with melanin granules; some epidermal cells receive melanin granules from the dendritic processes of more than one epidermal melanocyte.

Environmental and, consequently, hormonal stimuli appear to determine the effective population of epidermal cells for melanin transport within an 'epidermal melanin unit' by influencing the distribution of melanin within the dendritic processes of the melanocyte. This is most clearly demonstrated in animals adapted to a white background for extended periods of time. Owing to the perinuclear aggregation of melanin, few melanin granules pass into the dendrites and less melanin is found outside the

confines of the epidermal melanocyte. Therefore, in epidermal regions where 'epidermal melanin units' normally overlap, discrete units may now be found and are seen to be separated from other 'epidermal melanin units' by pigment-free epidermal cells (Fig. 1*C*). These results are clearly the reverse of those found in dark-adapted animals.

Our investigations indicate that there is a direct relationship between the distribution of melanin granules within melanocytes and the rate of melanogenesis. The dispersion of melanin granules within melanocytes is associated with a high rate of melanogenesis and release of melanin granules for transport by epidermal cells. The aggregation of melanin granules within epidermal melanocytes is associated with a lower rate of melanogenesis and little transport of melanin granules within epidermal cells. The patterns of melanin transport within the epidermis suggest an intermediate rate of melanogenesis where there is partial dispersion of melanin granules. Thus, it is possible that the hormones which regulate the distribution of melanin granules within melanocytes may also regulate melanogenesis. This finding confirms the earlier suggestion of Bábàk[8] that morphological colour change (quantity of pigment) in vertebrates is of necessity dependent on physiological colour change (distribution of pigment). The dispersion of melanin granules by hormones increases the opportunity for transfer of melanin granules to epidermal cells. Therefore, the rate at which melanin granules are carried away from melanocytes may also be a decisive factor in determining the rate at which they are synthesized. It remains to be established whether hormones act directly on the melanocyte or indirectly through the epidermal cells among which the melanocyte resides.

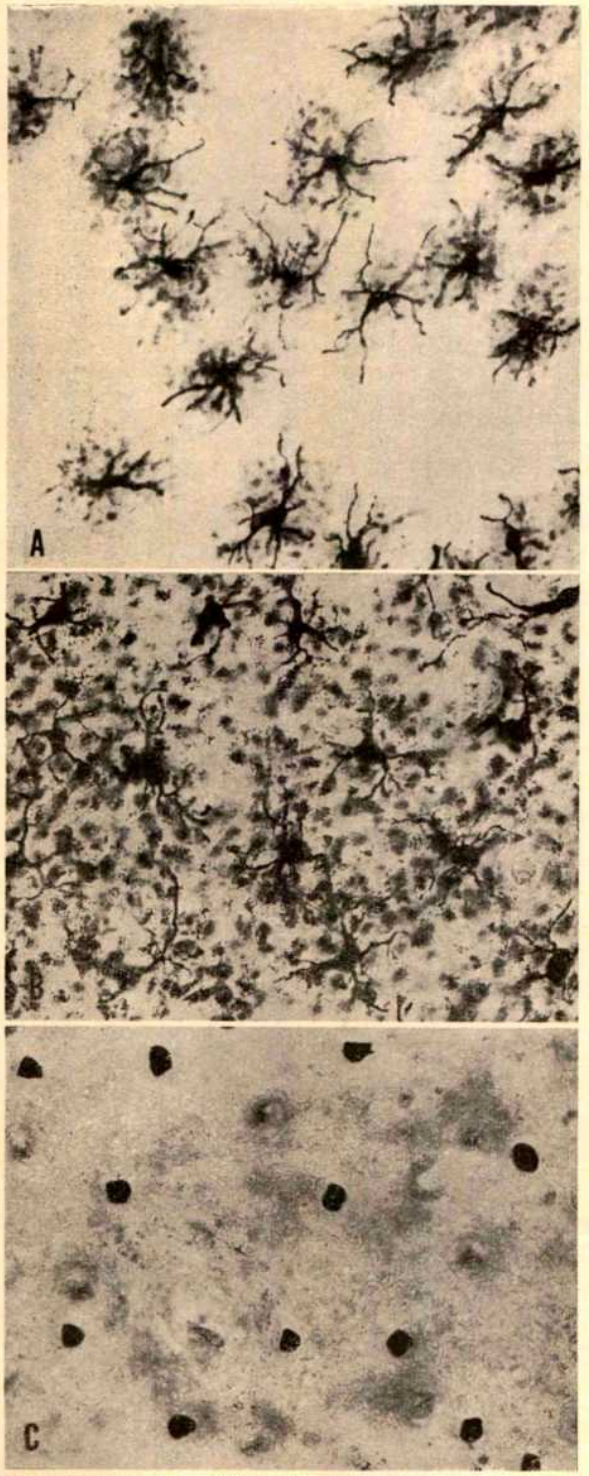

Fig. 1. Photomicrographs of the 'epidermal melanin units' of frog (*Rana pipiens*) epidermis: *A*, Little functional overlap among 'epidermal melanin units' in skin adapted to a neutral background; *B*, 'black-adapted' skin with 'epidermal melanin units' exhibiting functional overlap; *C*, 'white-adapted' skin illustrating perinuclear aggregation of melanin granules within melanocytes and absence of functional overlap among 'epidermal melanin units' (×600)

Lerner and co-workers[9] have postulated that hormones may influence melanogenesis within mammalian melanocytes by initial actions on the intracellular distribution of melanin granules. The rapid darkening of human subjects treated with melanocyte-stimulating hormone suggests that the dispersion of melanin granules within melanocytes may precede the onset of new melanin formation[9]. Snell[10], in a number of recent publications on mammalian pigmentation, has provided cytological evidence on the action of certain hormones on melanocyte morphology, melanin synthesis, and the release of melanin granules to surrounding malpighian cells. Snell has suggested that mammalian epidermal melanocytes react to these hormones in a manner similar to the dermal melanophores of amphibians. At present, there is no clear evidence that hormones bring about a reversible mobilization of melanin granules within mammalian melanocytes. The findings in amphibians reported herein suggest that such an action may well be demonstrated and indicate the importance of further work in this area.

Traditionally, the term melanophore has been used to designate a pigment-retaining cell with the capacity to disperse or aggregate its melanin granules[11]. The term melanocyte has generally been restricted to the neural crest-derived, melanin-forming cells of mammals and birds; melanocytes frequently secrete melanin granules into surrounding cells and until recently have been considered to lack 'melanophore action'. The 'epidermal melanocytes' of amphibians possess both capacities and indicate the need for a re-examination of this facet of pigment cell terminology. The vertebrate 'epidermal melanin unit' is a useful addition to pigment cell nomenclature and should lead to new light being shed on the integrated action of the diverse cell types associated with integumentary coloration.

INTRA-CELLULAR SITE OF EPIDERMAL KERATIN SYNTHESIS

By Dr. G. C. PRIESTLEY and Dr. P. T. SPEAKMAN

Department of Textile Industries, The University, Leeds, 2

At present it seems likely that the component molecules of fibrous proteins are biosynthesized in the same way as other proteins, in the sense that they have specific amino-acid sequences and molecular weights[1]. Experiments with many small proteins suggest that immediately after synthesis they spontaneously assume their native, three-dimensional arrangement[2]. As a result of the relative positions of positively and negatively charged, polar and non-polar side-chains, the native structure is the most stable in the physiological conditions inside or outside the living cell. The native structures of the components of fibrous proteins usually involve more than one protein molecule, each in a specific configuration and a definite position with respect to the others. Examples are the three chains of the tropocollagen molecule[3], the triplet of α-helices forming the protofibril of wool keratin[4], and the component molecules of myosin[5]. It is difficult to imagine that these native structures arise spontaneously when the component molecules come together *in vivo*. In the light of the available evidence of the mechanism of fibrous protein synthesis, and the preliminary examination of epidermal keratin biosynthesis described here, we suggest that fibrous proteins acquire their native structure at the time of synthesis. If the component molecules could be synthesized at the same place within the cell, and if the moment of starting and the rate of synthesis of the components could be controlled, then the native fibrous protein might well be the result. Our present experiments are designed to discover the intracellular machinery which synthesizes epidermal keratin and perhaps gives it its native structure. It may be larger and more elaborate than the polyribosomal aggregates found to synthesize small protein molecules.

Epidermal Sub-cellular Particles and Macromolecules

The skin on the ventral surface of the sheep's ear is relatively free from hair follicles. This makes the separation of dermis and epidermis easier and means that our examination of epidermal keratin synthesis is not confused by concurrent hair keratin synthesis. After the animals were killed about ten ears were kept in ice for about 2 h. The ears were cleaned with mild detergent, 0·5 per cent sodium deoxycholate (DOC) at room temperature, or wiped with cotton wool soaked with ether. Slivers of epidermis plus some dermis were cut with a razor and floated, epidermis upwards, on 0·01 per cent trypsin (Seravac Laboratories, once crystallized) in isotonic buffer (Oxoid 'Dulbecco *A*') adjusted to *p*H 7·8, for 30–45 min at room temperature. After this time the epidermis could be separated from the dermis, which was rejected, and washed in isotonic buffer. This and subsequent operations were carried out at 0° C. The epidermal preparation consists of dividing cells, which are the lowest layer, cells filling with epidermal keratin fibrils, and the fully hardened stratum corneum[6]. The preparation was washed quickly in hypotonic buffer (10^{-2} M *tris*(hydroxymethyl)aminomethane (*tris*), 10^{-2} M potassium chloride, $1{\cdot}5 \times 10^{-3}$ M magnesium chloride, *p*H 7·4) (ref. 7) and then allowed to swell for 5 min in 1·5 ml. of the same buffer. The preparation was homogenized by three stokes of the loose pestle and one of the tight in a Dounce homogenizer, and then centrifuged for 5 min at 1,250*g* to remove unbroken cells and tissue. The supernatant was made 0·5 per cent in DOC to remove ribosomes and ribosomal aggregates from the small amount of endoplasmic reticulum in epidermal cells, and if possible to prevent them from adhering to lipid droplets which contaminate the preparation. Fig. 1 shows the schlieren pattern 10 min after this supernatant from slow centrifugation had reached 50,740 r.p.m. in the Spinco model *E* ultracentrifuge. The pattern shows, from left to right, the lipid layer at the meniscus, a sharp peak due to epidermal macromolecules, proteins and nucleic acids, and then two small peaks caused by ribosomal sub-units and a sharper single ribosome peak.

Characterization of Ribosomes

The sedimentation coefficients of ribosomes and ribosomal sub-units are affected by the presence of macromolecules which alter the viscosity of the solution, and by temperature. Ribosomes and sub-units were prepared free from contaminating macromolecules by a method used by Earl and Korner[8]. All operations were carried out at 0° C. Epidermis was prepared as before, and washed three times by decantation after slow centrifugation with 0·2 M sucrose, 0·05 M *tris*, 0·005 M magnesium acetate adjusted to *p*H 7·6. The preparation was homogenized in the same buffer by five strokes of the loose pestle, and the homogenate was centrifuged for 10 min at 11,000*g* in a Spinco *SW*39 swinging bucket rotor in order to remove unbroken cells and tissue, nuclei, mitochondria and membranes. DOC was added to a final concentration of 0·5 per cent, and 4·25 ml. of this supernatant were carefully layered on to 5 ml. of a buffered, strong sucrose solution (1·0 M sucrose, 0·02 M *tris*, 0·1 M potassium chloride, 0·04 M sodium chloride, 0·005 M magnesium acetate, *p*H 7·6). Ultracentrifugation in a model *E*, *C* rotor at 105,000*g* for 4 h caused the ribosomes and sub-units to sediment through the lower, strong sucrose solution, while the macromolecules remained in the upper layer. The upper layer was removed using a Pasteur

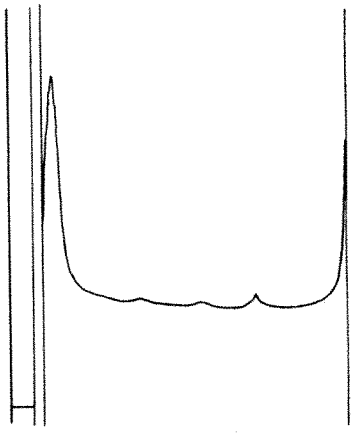

Fig. 1. Cell-free preparation from epidermis: schlieren pattern 10 min after reaching 50,740 r.p.m. Bar angle, 45°; 4° C. Sedimentation left to right

pipette. Then the lower layer was removed, and the pellet gently washed with an approximately isotonic buffer (0·02 M *tris*, 0·1 M potassium chloride, 0·04 M sodium chloride, 0·005 M magnesium acetate, *p*H 7·6) and re-suspended in the same buffer by carefully and repeatedly filling and emptying a hypodermic syringe with the solution. Ultracentrifugation in an analytical cell at 37,020 r.p.m. at two low concentrations of ribosomes allowed measurement of the sedimentation coefficients at 20° C, and s^0 was calculated assuming $1/s$ is proportional to concentration. The result, s^0 = 74 Svedberg units, is consistent with other mammalian ribosomes.

Incorporation Experiment

Epidermis was prepared as before and washed four times in isotonic buffer to remove trypsin. The pieces were then incubated at 37° C in 10 ml. Glaxo tissue culture medium 199 for about 30 min. The preparation was concentrated into about 1 ml. of medium by centrifugation at 1,250*g* for 2 min. Then, still at 37° C, 30 μc. of a carbon-14 labelled mixture of amino-acids (protein hydrolysate–^{14}C from *Chlorella vulgaris*, Radiochemical Centre, Amersham) were added in 0·3 ml. isotonic buffer. After 1 min excess cold isotonic buffer was added to stop amino-acid incorporation and to wash off excess labelled amino-acids. All subsequent operations were carried out at 0° C. Washing was repeated three times. The preparation was then washed quickly in hypotonic buffer, allowed to swell 5 min in the same buffer, and then homogenized in 2·5 ml. of the buffer. The homogenate was centrifuged 5 min at 1,250*g*, DOC was added, and 1 ml. was layered on to a 25 ml. linear sucrose gradient, 5–20 per cent sucrose dissolved in hypotonic buffer, in a cellulose nitrate tube. A further 1 ml. of the supernatant from homogenization was treated with 1 μg. ribonuclease (B.D.H.) for 10 min at 0° C, and layered on to a second gradient. After centrifugation for 90 min at 24,000 r.p.m. Spinco model *L–2*, *SW*25 rotor, the tubes were punctured with a hypodermic needle, and fifty-drop (about 1 ml.) fractions were collected. The fractions were diluted to 3 ml. and their optical densities were measured at 260 mμ using a Unicam *SP*500 spectrophotometer. Carrier protein (0·25 mg egg albumen in 0·5 ml. 4 N potassium hydroxide) was added to each fraction, and after 10 min the fractions were made 5 per cent in trichloroacetic acid in order to precipitate the protein. The precipitates were filtered off on 'Millipore' filters, the filter papers gummed to planchets, and the radioactivity of each fraction was measured using an end-window Geiger–Müller counter (Ericsson Telephones, Ltd.). Fig. 2 shows the result of the experiment without added ribonuclease. The optical density peak at about fraction 21, due to single ribosomes, had little radioactivity associated with it. In neither the optical density nor the counts per minute curves is there evidence of small polyribosomal aggregates usually found in rapidly dividing cells or in cells synthesizing small protein molecules. After 90-min centrifugation at 24,000 r.p.m. an aggregate of five ribosomes would be expected to appear in about fraction 10. The pellet was washed from the bottom of the cellulose nitrate tube; as before, carrier protein in potassium hydroxide was added, and total protein was precipitated by trichloroacetic acid. On a 'Millipore' filter the count of this precipitate was 365 per min. At present we are trying to discover the significance of the radioactivity in the pellet (i) by investigating the effect on it of different times and speeds of centrifugation of the supernatant from homogenization before layering on to the sucrose gradient; (ii) by collecting the pellet on a cushion of concentrated sucrose at the bottom of the sucrose gradient[9] instead of washing it from the tube; (iii) by fractionation of the pellet on sucrose gradients at lower speeds and for shorter times. When ribonuclease is added to the homogenate before density gradient centrifugation it has little effect on the result shown in Fig. 2 or on the radioactivity found in the pellet.

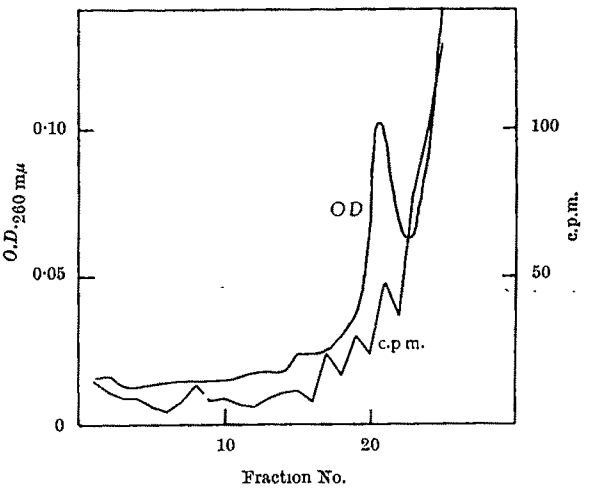

Fig. 2. Optical density and radioactivity of fractions from density gradient centrifugation of a homogenate from epidermis which had been incubated with carbon-14-labelled amino-acids

Discussion

The active units in the reticulocyte cell cytoplasm for the synthesis of haemoglobin sub-units are aggregates of four, five, or six ribosomes linked by a messenger–RNA strand[10]. In rapidly dividing cells, for example fibroblasts in culture dividing to form a monolayer on glass, similar small polyribosomal aggregates are the site of protein synthesis[11]. When the monolayer is complete, and rapid cell division has ceased, protein synthesis continues and the main product is now probably collagen[12]. Polyribosomes can no longer be detected in the cell homogenates. *In vivo* experiments confirm that collagen is not formed at small polyribosomal aggregates, but in subcellular fractions with *s*-values greater than 400, which are insensitive to ribonuclease treatment[13]. In adult rat heart muscle, small polysomes have been shown to be the site of protein synthesis[8]. However, the synthesis of heart muscle protein in chick embryo appears to be similar to collagen synthesis. Small polysomes are not detected; protein synthesis appears to occur in large ribonucleoprotein complexes which are disrupted by proteolytic enzymes[9].

There is evidence, therefore, that the fibrous proteins of muscle and collagen may be synthesized at large ribonucleoprotein complexes. We suggest that the native structure of fibrous proteins may arise as a result of concurrent synthesis of more than one polypeptide chain at these complexes. We are continuing to investigate the possibility that epidermal keratin may also be synthesized at a large ribonucleoprotein complex.

LETTERS TO THE EDITOR

ASTRONOMY

Evidence that the Dark Areas on Mars are Elevated Mountain Ranges

In the communication under the above title[1], Dr. Wells makes a good point in reference to Lowell's conclusion regarding Martian topography. It agrees in part with the phenomena I have often observed, namely, that the migration of portions of some maria and gradual shading off of some low-cloud or frost areas implies very gradual slopes[2]. But even in the case of abrupt topographic differences, I think Lowell was over-optimistic in his value of 2,500 ft. It must be remembered that the maximum phase occurs at about twice the oppositional distance. At that time the terrain slopes away from the observer at about 45°. Furthermore, the colour contrasts of both maria and deserts show a marked drop at about half the radius from the centre of the planet's disk, apparently from the Martian atmosphere. There is also the troublesome factor of irradiation. Mars has some twilight effects, further lessening the contrast. The total of these effects and the limitation of detail under the best 'seeing conditions' makes an abrupt topographic difference of 20,000 ft. or less impossible to detect.

I cannot reconcile the statement that the dark areas are elevated land. On the contrary, our observations show that the formation of localized clouds on Mars is a common occurrence, not a rare one. Many desert areas behave this way, such as: Elysium, Hellas, Isidis-Neith, Aeria, Edom, Nix Tanaica, Nix Olympica, Ogygis, and some other 'islands in the south'. In addition, there are some other areas exhibiting less whiteness and persistence. Meteorologically, the aforenamed regions must be the high-elevation areas and this is the basis for my topographic mapping of Martian desert-relief. The white areas strongly avoid the maria. Radiometric measurements show the maria to be warmer, which could be due to lower reflective power alone, but it is of the right sign to favour lower topographic altitude. The temperatures of our dark mountain forests are certainly lower than those of the brighter lowlands.

Recently, I presented evidence for the absence of folded mountain ranges on Mars[3]. Such mountains are of geosynclinal origin, in which erosional sediments are deposited into sedimentary rocks. There are good reasons why such conditions never prevail on Mars. On the other hand, the desert areas which are observed to whiten must represent plateaux. While most of these are round or oval in outline, at least two (Elysium and eastern Aeria) are definitely angular, suggesting fault-block terrain.

The relatively small number of minute white spots suggests that volcanism has operated on a much lesser scale than on the Earth. To my mind, and as I suggested in 1950, the round dark oases represent asteroid impact craters, which are much more numerous than the small white spots[4]. Fifteen years later this was confirmed by the *Mariner* 4 pictures.

Dr. Tombaugh's communication raises some interesting points about the topography of Mars. In view of the brevity of my earlier communication[1] I could only mention the most salient features of the proposed model for the dark maria. A more detailed discussion is now in preparation for publication.

One can scarcely doubt the rarity of Martian cloud phenomena if a comparison is made with some standard, say, one week's cloud occurrence on Earth. It is of interest to note that only one possible indication of the presence of a cloud was recorded by *Mariner* 4 although, admittedly, less than 1 per cent of the Martian surface was photographed.

Furthermore, the phenomena in the desert areas to which Dr. Tombaugh refers are quite different from those I gave as examples of lee-wave clouds. He has listed areas of possible hoar frost deposits on the surface which could imply elevated plateaux. (In my previous report I gave one example each of a possible mountain and plateau revealed by surface deposits of snow or hoar frost.) It is questionable that these areas participate in surface frost formation as frequently as has been observed. A powerful means of distinguishing between surface hoar frost and white clouds is by use of the polarimeter. For the past decade such observations at the Pic-du-Midi and Meudon have revealed that atmospheric clouds are as frequent a cause of brightening, particularly in the equatorial regions mentioned. The few instances that Dr. Tombaugh and others[2] have mentioned need not, of course, imply that all the bright areas (nearly three-quarters of Mars is bright desert area) are elevated. Since dust storms are considerably widespread occurrences, it would seem more natural that low areas would be dust covered and bright. Hence if the dark maria are depressions, why do they exhibit themselves at all? One would think that they would have been filled with dust and obliterated long ago. Application of Öpik's[3] 'rejuvenation' theory at this point would find even more stringent demands.

Figs. 29–31 of a recent publication by Dollfus[4] show the initial developments of the great dust storm of 1956. The dust clouds formed and spread along the bright regions between the dark maria without transgressing the boundaries. Later, of course, most of the maria became enveloped in some of the dust clouds. This phenomenon is certainly not consistent with the maria as depressions.

It may be that Dr. Tombaugh's "white areas strongly avoid the maria", but the white clouds (atmospheric phenomena) to which I have referred behave otherwise. They form at the interface of a bright and dark area, although they remain over the bright region and do not seem to penetrate the boundary into the mare. It was this peculiar 'stabilization' that caused me to suggest the similarity to lee-wave clouds on Earth. These Martian clouds are stationary but not unduly persistent, dissolving after several hours to re-form again the next day. One of the finest examples of these phenomena is depicted in Plates 33 and 34 in an article by Dollfus[5], where he describes them as: ". . . of the same nature as the bright formations observed at the top of the mountains surrounding the polar cap . . . and are probably also due to surface elevations". The bright formations in the polar regions to which Dollfus refers are ". . . bright, small clouds [which] appear in late spring each day at the same locations"[6].

In view of the mounting interest in the wind-blown formation theory of the dark maria beginning with McLaughlin[7], amended by Kuiper[8], and re-modelled by Rea[9], it appears that the interpretation of the dark maria

as elevations is finding increasing favour. At a recent symposium[10], Rea stated: ". . . the idea that the dark areas are depressed I find difficult to accept. Specifically, I know of no good evidence suggesting the dark areas are depressed".

The radiometric measurements mentioned by Dr. Tombaugh are worth considering; nevertheless, the difference in temperatures between the dark and bright areas is what would be expected on the basis of albedo differences alone provided, of course, that the thermal inertia of both regions is low and of comparable magnitude. The evidence derived chiefly from Sinton's[11] scans is still somewhat tenuous since they were averages of a few observations and not throughout an entire Martian year. Hence, it is not definitely known whether the dark areas maintain their higher temperatures over the complete Martian orbit or merely during the interval at oppositional passage. Observational bias would naturally disappear if the data extended over enough oppositions to make a statistically complete orbit.

Finally, I did not suggest any mechanism of mountain formation on Mars. To what extent crustal folding did or did not play a part does not preclude the existence of mountains. There are a considerable number of tectonic mountain ranges on the Moon.

To conclude, I find it strange that Dr. Tombaugh cannot believe the dark areas to be elevated when he himself states: ". . . the migration of portions of some maria . . . implies very gradual slopes". One can see that the nature of the topography of Mars is for the present of a highly speculative character and will remain so until the advent of orbiting reconnaissance probes.

The Radio Source Cassiopeia *A*

The high-resolution observations of the radio source Cassiopeia *A* by Ryle, Elsmore and Neville[1] show for the first time details of the structure of the source that suggest an interpretation of a feature of the nebulosity connected with the source the significance of which was not clear. The nebulosity is essentially a circular shell with an outer radius of 2·0 min of arc, but it shows a flare in position angle 70° that extends to a distance of about 3·8 min of arc from the centre[2]. The long streaks of nebulosity plotted by Ryle *et al.* at the east side of the source (α = 23h 21m 21s; δ = + 58° 33·5′ and α = 23h 21m 31s; δ = + 58° 33·1′) are the brightest features of the flare. They and the fainter details of the flare extend radially while the features of the shell show no strongly preferential direction.

The diffuse fast-moving condensations that form the shell are all inside of the shell shown by the source. The only filament plotted by Ryle *et al.* on the outer edge of the radio shell (α = 23h 21m 0s; δ = + 58° 31·1′) does not belong to the expanding shell, but is one of the semi-stationary filaments. The only part of the expanding nebulosity that extends beyond the radio shell is the flare; its outward motion is large, as one would expect, but could not be measured because all details are quite diffuse and change their shape rapidly. Relatively small negative radial velocities show that the flare moves in a direction at an angle of about 80° from the direction of vision, almost in the plane of the sky.

The contour map of the source shows a gap in the radio shell exactly coincident with the flare. If the shell structure of the source results from the compression of the surrounding interstellar medium by the expanding material, both the gap and the flare can be interpreted as due to locally very low interstellar density. If the material ejected in the direction of the flare encounters very low density only, compression will be negligible and the ejected material will move outward with negligible deceleration.

Two models are to be considered for the interpretation of the nebulosity: (*a*) one shell was ejected with high velocity which still persists almost unchanged in the flare while the rest of the nebulosity has been slowed down to its present velocity of expansion; (*b*) two shells with different velocities were ejected. The flare is a surviving part of a shell of material ejected with high velocity. In all other directions, this shell has encountered interstellar material of higher density, has compressed it and thus has formed the radio shell. A second shell of material ejected with lower velocity has followed the fast shell which has swept up the interstellar material so that the slow shell moves without deceleration. The circular shell of the nebulosity is the result of the slow ejection; its velocity of expansion has remained essentially unchanged.

Model (*a*) requires that the circular nebulosity has been slowed down considerably. In that case the age of 256 years estimated on the assumption of constant velocity of expansion[2] is too high. To explore the size of the error, we assume that the velocity v_s of the decelerated shell of radius r_s decreases as:

$$v_s = v_0/(1 + br_s^n) \qquad (1)$$

Integration gives:

$$v_0 t = r_s + br_s^{n+1}/(n + 1) \qquad (2)$$

The original velocity, still shown by the flare, is v_0. If r_f is the radial extent of the flare, $T = r_f/v_0$ is the true age; $\tau = r_s/v_s$ is the age determined on the assumption of expansion with constant velocity. Elimination of b from equations (1) and (2) leads to:

$$\tau = T[(n + 1) - nr_s/r_f] \qquad (3)$$

For the simple model of a shell slowed down by sweeping up of interstellar material of constant density with conservation of momentum[3,4], n equals 3 and the true age required by model (*a*) is then 110 years. The distance of 3,400 p.s.c., determined from the present velocity of expansion and transversal motion of the circular nebulosity, remains unchanged and stays in agreement with the observations of the 21 cm-absorption lines. The velocity of expansion of the flare, assumed to be the original velocity of all ejected matter, becomes 34,000 km/sec. A velocity of this order has not been observed in any supernova; it seems excessive and makes the one-shell model (*a*) unattractive.

The two-shell model (*b*) leads to a more acceptable interpretation. It admits constant velocity of expansion of the circular shell. The age of 256 years remains valid, the velocity of expansion of the slow shell is 7,400 km/sec and the velocity of expansion of the fast shell becomes 14,500 km/sec, comparable to the velocity of expansion of 12,000 km/sec observed in the supernova in *NGC* 4303 (1961) (ref. 5).

This supernova is an unusual object. It is clearly not a supernova of type I. It has some similarities to supernova

of type II, but differs so much from typical supernovae of that type that Zwicky[5] suggests that it is a supernova of a new type III. Its early spectrum is continuous and blue, as are the spectra of type II supernovae, but it remains in this phase for several weeks, much longer than supernovae of type II. The decline of the light from the maximum is much slower than in supernovae of type II, and the levelling-off of the light curve, shown by most supernovae of type II, occurs much later and after a much greater decline. The line spectrum that eventually emerges is similar to that of supernovae of type II, except for the much larger velocity of ejection. The slow initial changes of light and spectrum suggest that the ejected mass is much larger than that ejected by supernovae of type II. No information is available on the detailed structure of the emission lines; it is thus not possible to judge whether more than one shell was ejected. In some supernovae of type II, multiple absorption lines show the presence of two or three shells.

The information now available on the structure of the source and of the nebulosity seems to be consistent with the interpretation that the two-shell model (*b*) is acceptable and that Cassiopeia *A* is the remnant of an unusual supernova similar to the supernova in *NGC* 4303 (1961) rather than the remnant of a typical supernova of type II.

COSMOLOGY

Why is the Sky Dark at Night?

Bondi[1] has pointed out that with certain very general assumptions, notably the cosmological principle, it can be inferred from the observed darkness of the night sky that the universe is either young or expanding. Harrison[2] has discussed the same question from a somewhat different point of view. He considered evolving world models populated by stars of fixed luminosity and finite age and concluded that "the night sky is dark simply because the stars are so widely separated from each other . . .; . . . the radiation level is affected only in a comparatively slight way by whether the universe is expanding or contracting . . . ". Although Harrison's argument is mathematically correct, his models are somewhat unrealistic. The present communication shows that the darkness of the night sky actually has a number of distinct causes, among which the one given by Harrison may not be especially important.

It can be shown that the density of radiation in a uniform and uniformly expanding universe of zero spatial curvature is given in the grey-body approximation (absorption coefficient independent of frequency) by the formula

$$E_0 = \int_{t_i}^{t_0} [S(t)/S_0]^4 \exp\left[-\int_t^{t_0} \frac{du}{\tau(u)}\right] j(t)dt + E_i\left(\frac{S_i}{S_0}\right)^4 \qquad (1)$$

where E_0 represents the mean energy density of radiation, $S(t)$ is the cosmic scale factor, $j(t)$ is the volume emission coefficient (integrated over frequency) and τ is the inverse absorption probability per unit time, assumed to be independent of frequency. The suffixes 0 and i refer respectively to the present epoch and to an arbitrary 'initial' epoch. The integral in equation (1) has the following interpretation. In the absence of absorption, the density of radiation emitted during the time interval $(t, t + dt)$ would have been reduced at time t_0 by the factor $(S/S_0)^4$, owing to dilution resulting from the cosmic expansion and to the redshift. The exponential factor represents the probability that a photon emitted at time t will survive until time t_0. The second term on the right side of (1) comes from the initial radiation field.

In a static universe, S, j, and τ are all constant, and we have:

$$E_0^* \equiv E_0 - E_i = j_0\tau(1 - e^{-T/\tau}),\ T = t_0 - t_i \qquad (2)$$

When $T \ll \tau$, $E_0 = jT$. When $T \gg \tau$, $E_0 = j\tau$, which is Olbers's result, since in a universe populated by stars, $\tau = (n\sigma c)^{-1}$, where n is the number density of stars and σ is the geometrical cross-section of a star; thus in this case $E_0 = E_s$, the radiant energy density at the surface of a star.

In a steady-state universe $t_i = -\infty$, $S_i = 0$, j and τ are constants. $S(t) = \exp(t/T)$, and we may set $t_0 = 0$. We then have:

$$E_0 = j_0\left[\frac{4}{T} + \frac{1}{\tau}\right]^{-1} \qquad (3)$$

If $T \ll \tau$, $E_0 = 1/4\ jT$. If $T \gg \tau$, we again recover Olbers's result, $E_0 = j\tau$.

Finally, in an evolving universe, $t_i = 0$, $S \sim t^{2/3}$ as $t \to 0$, and $E_iS_i^4 \to$ constant as $t_i \to 0$. In the model discussed by Harrison[2], $j \sim n \sim S^{-3}$ and $\tau \sim n^{-1} \sim S^3$. Since S is an increasing function of t, it is clear that under these assumptions the major contribution to the integral in (1) comes from values of t not very different from t_0. Thus, as Harrison emphasized, this case is qualitatively similar to the static case. But the assumption that the ratio of luminosity to mass is constant in an evolving universe is highly artificial. Both the lifetime and the mass-to-luminosity ratio of a star decrease rapidly with increasing mass. As we go backward in time, we should accordingly expect to find an ever-increasing proportion of high-luminosity stars and hence an ever-increasing value of the quantity (jS^3). If this quantity were to increase faster with decreasing t than $S^{-1}(t)$, the qualitative similarity between the evolving case and the static case would be destroyed.

For sufficiently small values of t, a nearly uniform distribution of fully or partially ionized gas must prevail. The dominant contribution to the emission coefficient j will then be from free–free emission, so that $j \sim n^2 \sim S^6$. This emission has been studied in detail by Miss Kaufman[3]. At radio wave-lengths it contributes much more to the background sky brightness than does stellar radiation. It can easily be found that the contribution to the background radiation density from free–free emission is given in the grey-body approximation by:

$$E_0\ (\text{free–free}) \doteq \Gamma\left(\tfrac{1}{3}\right)(S_1/S_0)^4 j_1\tau_1 \qquad (4)$$

where the suffix 1 refers to the epoch at which the characteristic absorption time τ is just equal to the age of the universe:

$$\tau_1 \equiv \tau(t_1) = t_1 \qquad (5)$$

Formula (4) shows that the brightness of the night sky is finite for the reason given by Olbers: the radiating material is opaque, whence the factor $j_1\tau_1$. The night sky is dark because of the expansion, which is responsible for the factor $(S_1/S_0)^4$.

To sum up: the intensity of the background radiation field is limited by quite distinct physical effects in the three cosmologies considered here. In a static universe it is limited (under present conditions) by the finite lifetime of the stars. In a steady-state universe the darkness of the night sky is a direct consequence of the cosmic expansion. In an evolving universe, the situation is more complex. The stellar contribution to the background radiation field is limited in part by the finite lifetimes of stars and in part by the cosmic expansion. At radio wave-lengths, free–free emission at an early stage in the cosmic expansion may be the most important contributor.

The intensity of this radiation is limited partly by opacity and partly by the cosmic expansion. In addition, a vestigial radiation field, represented by the second term on the right side of (1), may be present. Arguments in favour of such a field have appeared in the recent literature.

GEOPHYSICS

Collision-induced Absorption in the Earth's Atmosphere

MOST of the absorption which occurs in the atmosphere in the infra-red region is due to the minor constituents such as water-vapour, carbon dioxide and ozone. The major constituents oxygen and nitrogen possess no dipole moment so that their vibrational and rotational energy states cannot be excited directly by absorption of radiation. However, dipole moments are induced during collision processes; transitions due to these can be seen in very long absorbing paths such as are present in the atmosphere. This report shows that absorption in the solar spectrum near 4·2μ is due to collision-induced absorption by nitrogen, and presents a short discussion of the importance of the rotational collision-induced bands of oxygen and nitrogen in the radiation budget of the atmosphere.

Williamson and Houghton[1] considered collision-induced absorption in the atmosphere and showed that, providing temperature variation of the absorption coefficient can be neglected, the transmission τ of a slant path at zenith angle θ extending from the top of the atmosphere down to the level where the pressure is p atmospheres (1 atmosphere = 10^6 dyne cm^{-2}) is:

$$\tau = \exp\left(\frac{-kcp^2H \sec\theta}{2}\right)$$

where k is the absorption coefficient expressed in cm^{-1} (atm.)$^{-2}$, c is the volume fraction of the absorbing gas present in the atmosphere (0·8 for nitrogen), and H is the atmospheric scale height ($\simeq$ 8 km). The absorption due to collision-induced processes is not only dependent on the amount of absorber in the path, but also on the frequency of collisions; the p^2 term in the exponent arises from these two factors.

The fundamental vibration frequency of nitrogen lies at 2,331 cm^{-1} so that the centre of the band is completely obscured by the ν_3 band of carbon dioxide centred at 2,349 cm^{-1}. The carbon dioxide band terminates on its short wave-length side in the band head at 2,397 cm^{-1} and it is therefore possible that, if the nitrogen band is sufficiently broad, absorption due to it will be seen at a higher frequency than 2,397 cm^{-1}. The solar observations summarized by Farmer and Todd[2] and the horizontal path measurements of Berry, Farmer and Lloyd[3] show that there is some absorption there which has not been accounted for. In order to test whether in fact this is the case, some measurements on synthetic nitrogen and carbon dioxide atmospheres have been carried out in the laboratory using a 15 m multitraversal sample cell in which path lengths of up to 1 km can be obtained.

Fig. 1 shows a laboratory spectrum for 720 atm. cm of nitrogen containing a small amount of carbon dioxide (0·5 atm. cm). The spectrum was taken at a total pressure of 1 atm. The S-branch of the nitrogen collision-induced band can be clearly seen on the high-frequency side of the carbon dioxide band. From a series of measurements made on nitrogen at pressures up to 2 atm. the transmittance τ of a path of length l was shown to be of the form:

$$\tau = \exp(-kp^2l)$$

which is consistent with the 'pressure squared' behaviour for collision-induced absorption. The absorption coefficients determined from these measurements are in good agreement with the values obtained recently by Gush[4] and by Reddy and Cho[5] at higher pressures. Using the coefficients obtained in this way, spectra were computed for the conditions of observations which have been made in the Earth's atmosphere. Fig. 2 shows solar spectra taken from sea-level (curve A) and from 5·2 km altitude

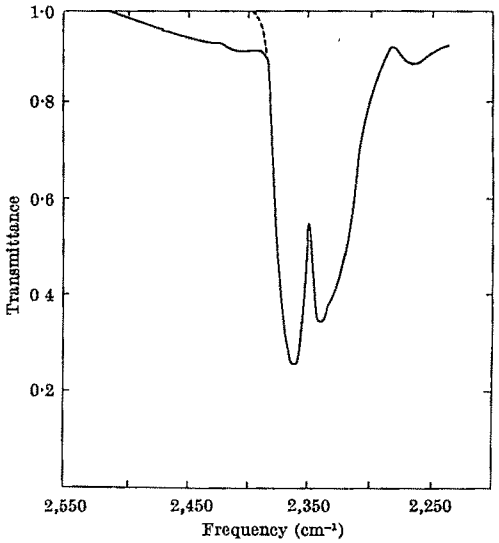

Fig. 1. Laboratory spectrum of nitrogen with carbon dioxide impurity. Nitrogen, 720 atm. cm; carbon dioxide, 0·5 atm. cm; total pressure 1 atm.

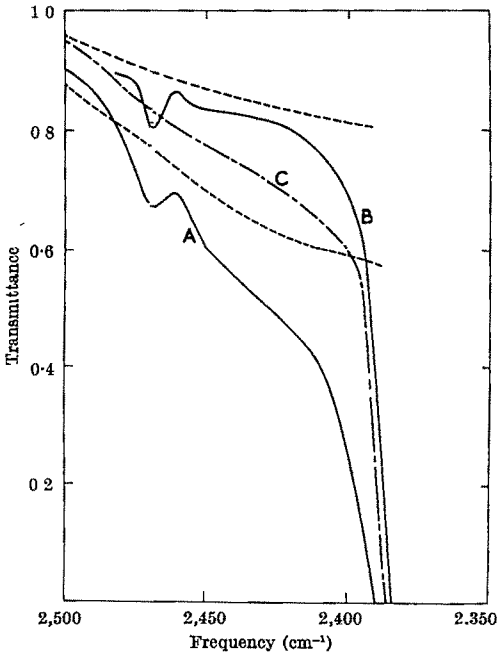

Fig. 2. Solar and horizontal path spectra on the high-frequency side of the ν_3-carbon dioxide band. A, Solar spectrum from sea-level, $\theta = 46°$; B, solar spectrum from 5·2 km altitude, $\theta = 11°$; C, 8·4 km horizontal path at 5·2 km altitude

(curve B) ($p \sim 0{\cdot}5$), together with a horizontal path spectrum at 5·2-km altitude (curve C) measured over a path of 8 km length (that is, a path containing the same number of molecules as a zenith path from the same base altitude). It can be seen that there is a significant difference in absorption from 2,400 to 2,500 cm^{-1} when all the nitrogen present in the atmospheric path is at the base altitude pressure (comparing curves A and C). Furthermore, the increase in the distortion of the shape of the solar spectrum produced by the nitrogen, as the base altitude is lowered, is also evident (comparing curves A and B). The dotted lines indicate the computed contribution to absorption by nitrogen under the conditions of the two solar spectra.

The other collision-induced bands which occur in the atmosphere are the fundamental vibrational band of oxygen at 1,556 cm^{-1}, and the rotational bands of oxygen and nitrogen which extend downwards in frequency from about 300 cm^{-1} with their centres at about 100 cm^{-1}. The vibrational band of oxygen was observed by Crawford, Welsh and Locke[6]. It is completely obscured by the ν_2 band of water-vapour. It contributes very slightly to radiative exchange in the upper troposphere (see ref. 1).

The rotational bands have been observed by a number of workers, most recently by Bosomworth and Gush[7]. At the wave-length of the atmospheric window at 29 cm^{-1} (see ref. 8), they account for 22 per cent absorption in a vertical path of atmosphere from sea-level; this is almost entirely due to nitrogen. Otherwise, so far as the lower atmosphere is concerned, they are completely obscured by the rotational band of water-vapour. If the water-vapour content higher in the troposphere is very low, these rotational bands can have a small effect on the radiative budget, adding to the radiative cooling there by up to 0·1° C day^{-1} at 500 mbars and 0·03° C day^{-1} at 200 mbars.

We thank Mr. T. M. McCormick and Mr. J. E. A. Selby (E.M.I. Electronics, Ltd.) for assistance with the measurements and computations described here.

Correlation of Dust and Ozone in the Stratosphere

The vertical distribution of dust and ozone was measured on a series of five balloon flights over Minneapolis, Minnesota. The ozone detector was of the chemiluminescent variety, while the dust detector was a modified version of the one described previously by Rosen[1]. Both detectors were flown on the same balloon but were electrically and mechanically separated.

The results show that above the dust maximum (5 km above the tropopause) there is apparently no appreciable correlation of dust and ozone; that is, the ozone profile can have considerable structure, but the dust profile is always relatively smooth. A thin dust layer of significant concentration was never observed in this region. Pittock[2] has described a persistent dip on the ozone concentration at 21 km and suggested that it was due to the destruction of ozone by a thin volcanic dust cloud. Such an explanation seems rather unlikely in view of experimental evidence.

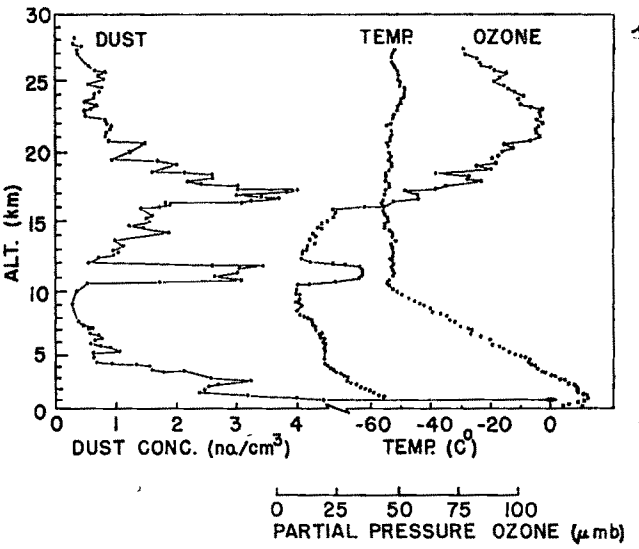

Fig. 1. The dust and ozone distribution over Minneapolis, Minnesota, on December 22, 1965. The dust concentration refers to particles larger than 0·25μ in diameter

The region between the dust maximum and the tropopause is characterized by layers rich in both dust and ozone. An example of this phenomenon is shown in Fig. 1. These layers were named ozone rivers by Kroening and Ney[3] before it was known that they also contain dust. The life of these rivers is probably much too short for the dust to have any noticeable effect on the ozone concentration.

I thank John Kroening for use of his ozone data before publication. This work was supported by the Office of Naval Research.

PHYSICS

Airborne Observations of Natural Radioactivity

Under the above title Warburton, Fookes and Watt[1] have described some measurements performed in June 1959 in Australia with a scintillation detector at altitudes up to 3·6 km. The day-to-day variations found by the authors "were surprisingly large and were found to occur mainly in the atmosphere between the ground and temperature inversion layers". They concluded that it was probably mainly radon and its decay products which were detected and attributed their γ-counting to the γ-rays from lead-214 and bismuth-214, estimating that a record of 8 c/s corresponds to 10^{-17} c./cm^3 of radon of a uniform concentration.

I should like to direct attention to the following two points: (1) the reaction of the probe by Warburton *et al.* on cosmic rays; (2) the results of the direct determination of the radon content of free atmosphere at different altitudes made as early as 1928 by Wigand and Wenk[2]. In fact the curves produced by Warburton *et al.* for the count rate versus altitude have an almost identical course from 2·5 km upwards which agrees fairly well with the assumption that at these heights the probe used registers mainly the cosmic rays. This conclusion is corroborated by the

results of Wigand and Wenk who found the following range of values in a series of airplane measurements:

Altitude (km)	Radon content (10^{-16} c./cm^3)
0·35–1·5	4·28–28
2·0 –2·3	0–24

The regular course of the curves reproduced by Warburton *et al.*[1] from 2·5 km upwards is in agreement with Wigand and Wenk's finding that practically no radon exists above 2·5 km. With regard to their short life-time, it is unlikely that lead-214 and bismuth-214 could ascend from lower altitudes to those explored by Warburton *et al.* and be detected by scintillation counter.

The large variations in counting at lower altitudes, and mainly under the temperature inversion layers, agree with the findings of various authors before the Second World War, that at such atmospheric conditions the radon content varies erratically and sometimes presents exceptionally high values near the inversion layers[3].

On the Combination of an Electron Spin Resonance Spectrometer and a Multichannel Analyser

In a recent communication, Kent and Mallard[1] pointed out that the versatility of an electron spin resonance-spectrometer can be considerably improved by combining it with an analogue digital converter and a commercial multichannel analyser as they are commonly used in nuclear spectroscopy. We have used a similar piece of equipment, and have already presented a preliminary report[2]. The basic technique was introduced by Klein and Barton[3]. It should be noted that any real improvement is based on the fact that the noise seen in electron spin resonance-spectra is not 'white noise'. That is to say that the probability for a certain frequency to occur in the noise-spectrum is not equal for all frequencies, but is enhanced for lower values[3]. It is therefore clear that no higher sensitivity can be achieved if the time constant of the amplifier and the recording time are enhanced above a certain limit being about 100 sec for the time-constant[4]. The sensitivity is restricted, for example, by instabilities of the whole equipment. This applies to relatively long times of measurement. If the recording time is short, a sampling procedure as described by Kent and Mallard[1] is not expected to bring any improvement if the time-constant is correctly adjusted. Thus the subdivision of one measurement into ten single ones appears to offer no advantage and the same result may be obtained by increasing the apparatus time constant or by repeating ten times the recording of the whole spectrum at a higher speed. The basic law of communication theory, namely, that any improvement in signal-to-noise ratio requires an increase in time of measurement, cannot be overcome by any of these methods.

We have used an '*AEG*'-electron spin resonance-spectrometer (12-cm magnet) in combination with a self-designed analogue-digital converter and a commercial 'Intertechnique'-400-channel analyser. In order to ensure correct superposition of the spectra, the start of each measuring cycle is triggered by a signal from a nuclear magnetic resonance magnetic-field meter, shaped by a special circuit, to the flow-time input of the analyser. Thus it was possible to superpose more than 1,000 single spectra yielding an improvement in signal-to-noise ratio by a factor of more than 30.

In preliminary experiments we were able to detect 10^{-7} M Mn^{2+} in aqueous solution. A more detailed account of our device and the measurements carried out will be published elsewhere.

[4] Schneider, F. (personal communication).

We agree in principle with the conclusion of Kiefer and Neubacher on the multi-sampling method. However, this was not the main point of our communication—this sort of work has been introduced before by Klein and Barton; our interest lay mainly in the other versatile features that we described. We have, however, some comment to make, following this note by Kiefer and Neubacher. They say that the same result (as the multi-sampling method) is obtained by (i) increasing the apparatus time constant, or by (ii) repeating 10 times the recording of the whole spectrum at a higher speed (with single samples per channel, and, we presume, with a shorter time constant).

We assume by (i) that they also mean that the duration of the sweep should be increased as the time constant has already been selected as optimum for the spectrum involved and any increase in the time constant, without a proportionate increase in sweep period, would result in distortion of the spectrum. The advantage of this would then appear to be obscure since to achieve the same result one would need to take a longer time.

Statement (ii) appears to be merely a reiteration of our statement that N sweeps of a spectrum, with 10 samples of signal and noise per channel per sweep, represent $10N$ faster sweeps. We admit our error in failing to add the important point that we meant 'faster sweeps'. It has been our experience that, whenever the sensitivity of instruments has been in dispute, the contenders frequently fall into the trap of failing to state all the conditions under which the sensitivity was measured, such as time constant, sweep speed, and so on. It would appear that we also have fallen into this trap on this occasion.

We found on our machine that, as we stated in our original communication, interference from 50 c/s ripple coherent with the analyser channel periods tended to obscure information so that, if we performed $10N$ fast sweeps, the 50 c/s ripple would be accentuated $10N$ times, whereas by performing N slower sweeps with 10 multi-samples, this does not occur. We would, however, hasten to add that the multi-sampling method has no advantage over single-sampling methods when enhancement of signal-to-noise is related to the result of just one sweep performed in the same time at the same time constant. We hope that we have now made this point clearer.

Asymmetric Nuclear Fission and the Liquid Drop Model

In a previous article[1] we directed attention to the resemblance between curves representing the division of electrically charged liquid drops and mass yield curves for nuclear fission.

More recently, we have become aware of fission yield data which further illustrate this resemblance. The two sets of curves in Fig. 1 are a photograph of original drawings. We reproduce, on the left, the fission yield obtained by Gibson[2] for fission of plutonium-239 induced by bombardment with deuterons of various energies, and, on the right, Fig. 5 of our previous paper[1]. In the latter we had plotted the fractional energy change, E_f, versus the fractional volume change, V_f, for the division of a surface-

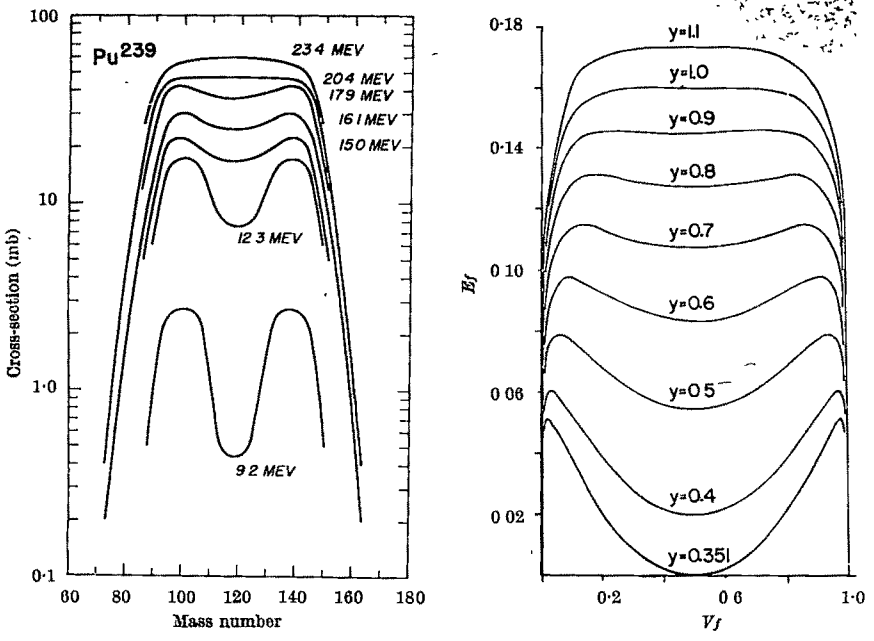

Fig. 1. On the left, fission yield for fission of plutonium-239 induced by bombardment with deuterons of various energies, on the right, the fractional energy change, E_f, plotted against the fractional volume change, V_f, for the division of a surface-charged drop

charged drop. A V_f value of 0·5 corresponds to symmetric division. The parameter y is defined as:

$$y = Q^2/16\pi R^3\gamma$$

where Q is the charge on the drop, R the radius and γ the surface tension.

It is remarkable that curves based on energy considerations in the division of a surface-charged drop resemble the experimental fission yield curves so closely in shape and form for 'y' values between 0·7–1·1, and deuteron energies between 15·0–23·4 MeV, respectively. In making this comparison we assume a relation between the ordinates (energy and cross-section) and between the abscissae (drop volume and mass number).

The traditional liquid drop model considers the nucleus as a drop of incompressible fluid with a spherical shape at equilibrium and with a uniform and constant volume charge. The process of fission is thought of as a competition between the long-range Coulomb forces throughout the volume of the drop and surface forces representing the effect of non-saturation of the short-range attractive forces at the nuclear boundary. Quantum mechanical effects, such as tunnelling and shell structure, are not a part of this model.

It has become customary in the liquid drop model to introduce a fissionability parameter x which is defined as:

$$x = 3(Ze)^2/40\pi R^3\theta$$

where Ze is the nuclear charge and θ the nuclear surface tension. Thus the parameter x for the volume-charged drop is analogous to the parameter y, already noted, for the surface-charged drop.

Central to the following argument is the difference in behaviour between a volume-charged drop of fixed-charge density and a surface-charged drop for which instantaneous charge redistribution is allowed.

A simple approach to binary division is made by considering the final Coulomb and surface energy of the system. It has been shown[1,3] that for a volume-charged drop, independent of the value of x, the final energy will be a minimum when the drops formed are of equal radius.

As the minimum final energy of the system predicts symmetry, attempts have been made to explain the asymmetry of nuclear fission by a computation of the energies of the saddle shapes which are intermediates in the fissioning process. The usual method is to represent small deformations of the drop by an expansion of its radius, R, in terms of Legendre polynomials. Frankel and Metropolis[4] computed symmetrical deformations on the 'Eniac', with expansion of R up to and including the tenth Legendre polynomials. The effect of the introduction of asymmetric terms in their calculation was that the energy increased, and they concluded that for $x \geqslant 0{\cdot}65$ the saddle configuration is a purely symmetric deformation. More recently, Cohen and Swiatecki[5] found the saddle shapes stable against asymmetry down to $x = 0{\cdot}394$.

It appears, therefore, unlikely that the saddle shape energies will provide an explanation of asymmetry on the basis of the present volume-charged drop model. However, from the point of view of our argument, the consideration of the saddle shapes as such has an additional significance.

Suppose there is for some value of 'x' an asymmetric shape at the saddle point. Such a shape must be the precursor for the asymmetry of the fragments. Implicit in this supposition is the necessary conclusion that in its final state the system is not at the energy minimum, the reason being that for a volume-charged drop, as already pointed out, drops of equal radius correspond to the energy minimum for a binary division.

We return now to the division of a surface-charged drop. In this case a pair of asymmetric droplets[1] represents the lowest final energy state for any value of $y < 1$. Furthermore, the experimental evidence (Fig. 2, ref. 1) shows that the degree of asymmetry of the saddle shapes is approximately the same as that of the final droplet pair. In this instance, it is not a necessary conclusion that the system cannot attain the lowest final energy state.

At the point of separation during the division of a surface-charged drop, the two droplets are connected by a thin neck (Fig. 3, ref. 1), and are at the same electrical potential (ref. 1). On the other hand, the division of a volume-charged drop leads to the formation of two droplets which have the same charge to mass ratio whatever their relative size. Hence, for volume charge, only droplets of the same size have the same potential.

It is suggested that a liquid drop model of the nucleus in which charge redistribution is admitted will account for the asymmetry of nuclear fission as such. Furthermore, this model predicts the change of asymmetry as a function of the energy of the bombarding particle. The degree and mechanism of charge redistribution are matters for further investigation.

Superiority of Atomic Mass per Nucleon as a Parameter for Nuclides rather than the Conventional Packing Fraction

The results of the calculations undertaken by Prof. Durnford[1] are very interesting, and enable him to claim "uniqueness of the mass-surface relative to iron-56".

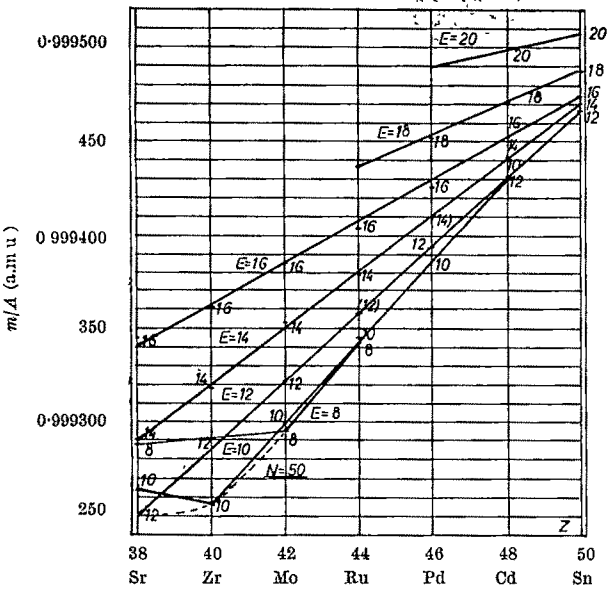

Fig. 1. $Z=38 \cdots N=50 \cdots Z=50$ Excess number $E=N-Z=A-2Z$

Actually, what Durnford has brought to light is the ambiguity of the packing fraction as a parameter. This ambiguity can be avoided simply by using the atomic mass per nucleon (m/A) as the parameter for nuclides instead of the packing fraction, thereby freeing the calculations from any dependence on particular standards of atomic masses. Incidentally, $^{56}_{26}$Fe competes with $^{62}_{28}$Ni for the minimum mean nucleon mass value[2].

The superiority of the mean nucleon mass as a parameter is especially emphasized by plotting (m/A) for a nuclide against its atomic number Z and denoting each point by its neutron excess number $E = N - Z = A - 2Z$ (ref. 3). Points of equal E then form straight or 'isoexcess' lines, which break off and start again with new slopes at magic numbers in N and Z. The magic numbers occurring here are first of all those discussed fully by Mayer and Jensen[4], and a set of as many again, which could be called sub-magic numbers, and which are easily fitted into the Mayer-Jensen shell structure.

The plotted points fall on the isoexcess lines with an accuracy of within 2×10^{-6} atomic mass units per nucleon —this being far more accurate than that of any mass formula so far available[5].

Since the aforementioned system of atomic masses was introduced[3], it has been used to correct and predict the atomic masses of a number of nuclides to the mentioned accuracy.

A sample plot of isoexcess lines appears in Fig. 1.

Electric Breakdown in Non-virgin Gases

ALTHOUGH the mechanism of the electric breakdown of atomic and molecular gases at low pressure is well understood[1], most investigations have been confined to gases in the virgin state—that is, when the atoms or molecules are in potential energy states corresponding to the ambient temperature and pressure. However, the collision processes involved are substantially altered if the gas contains species with large potential energy, such as excited atoms or molecules at room temperature.

Recent observations on nitrogen show that the breakdown potential is reduced by $\leqslant 10$ per cent when a small number of excited molecules of nitrogen (N_2*) is added to the virgin gas at pressures of about 1–10 mm mercury. To avoid contamination, a long glass tube 4 cm in diameter is filled with spectroscopically pure nitrogen and the breakdown potential at 15 Mc/s is measured with external electrodes at one end of the tube while at the other end, at a distance of up to 60 cm, N_2* with a long free-life (order 1 sec) is produced by an independent auxiliary discharge. By a series of experiments[2], other factors which could be responsible for the reduction in breakdown potential have been excluded such as impurities, pick-up, diffusing electric charges, light and thermal changes. The reduction observed depends on the strength of the auxiliary discharge, its distance from the region measured, and on the pressure. A similar effect has been observed in exploratory experiments in hydrogen.

The presence of active molecular species carrying potential energy of several eV has been demonstrated by a new detection method: N_2* interacting with a metal oxide can reduce its order by one. For example, the white-yellowish trioxide of molybdenum is changed to the lead-grey dioxide. This and other metal oxides, such as vanadium pentoxide and tungsten trioxide, were exposed to N_2* diffusing from the auxiliary discharge. The time was recorded after which a clearly observable colour change occurred when the powdered oxides are placed at different distances from the auxiliary discharge. These experiments confirm that potential energy carriers diffuse relatively slowly down the tube. From the chemical energy balance and by assuming that the colour change corresponds to a certain thickness of the de-oxidized layer, a lower value of the concentration of excited particles can be estimated. This is compared with the concentration necessary to account for the reduction in breakdown potential by pre-excitation. The de-activation of N_2* by spontaneous radiation is strongly forbidden and that by collision with nitrogen molecules is a rare process[3]. Since N_2* is produced in a relatively weak discharge, nitrogen atoms can be taken to be absent[4].

It is concluded that the reduction in breakdown field is due to the presence of a distribution of vibrationally excited molecules in the ground state or in a higher electronic state[5]. These molecules possess virtually lower ionization potentials than nitrogen in the ground state, possibly with larger ionization cross-sections. Also in nitrogen a very small fraction of the electrons have energies above ionization energy and the population of excited molecules produced before breakdown is small, whereas in a pre-excited gas their population is considerably increased so that a large fraction of electrons previously unable to ionize can now contribute to ionization by collision.

CHEMISTRY

Effect of Arsenic Pressure on Dislocation Densities in Melt-grown Gallium Arsenide

In the course of an investigation into the growth of gallium arsenide crystals in a horizontal Bridgman apparatus, it was found that the dislocation density at the centre of the cross-section of ingots increased with increasing arsenic vapour pressure in the ampoule during growth. The crystals were grown by moving the charge contained in a sand-blasted silica boat through a temperature gradient of about 10° C cm^{-1} at a rate of 0·5 cm h^{-1} (ref. 1). No seed crystal was used. Using the data of Honig[2], the arsenic pressure was estimated from the temperature of a thermocouple at the coolest point of the sealed growth ampoule where the excess arsenic condensed. Dislocations were detected by etching *A* faces of (111) oriented slices with a mixture of two volumes of water, one volume of nitric acid and one volume of hydrochloric acid after grinding with 15μ alumina and polishing with a mixture of two volumes of water, three volumes of nitric acid and one volume of hydrofluoric acid.

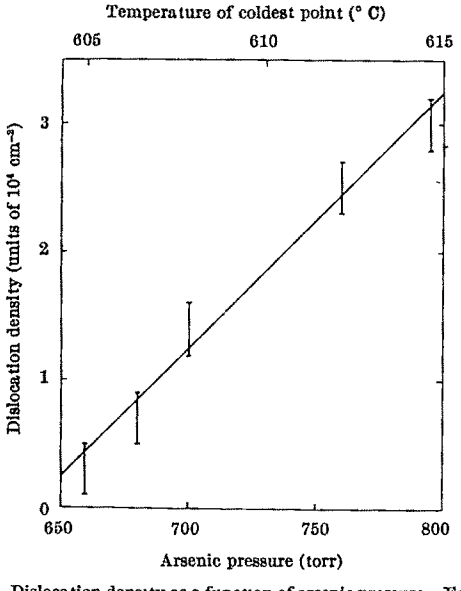

Fig. 1. Dislocation density as a function of arsenic pressure. Each point is the mean of five observations

The results obtained are shown in Fig. 1 and suggest that vacancy condensation to form dislocation loops[3,4] is probably one mechanism responsible for the introduction of dislocations into melt grown gallium arsenide. Work on the phase diagram of the system[5–8] suggests that material with maximum melting point is in equilibrium with about 720-torr pressure of arsenic. In accord with this, when pressures less than 650 torr were used, traces of constitutional supercooling were seen, suggesting the presence of excess gallium in the melt. At pressures greater than 800 torr, blow holes formed, as would be expected if the melt contained excess arsenic. The monotonic increase of dislocation density is difficult to account for in terms of strains due to residual constitutional supercooling. However, if a vacancy mechanism is responsible, the use of the Schottky product shows that minimum total concentration of vacancies would occur at the stoichiometric composition. Since the dislocation densities shown in Fig. 1 increase monotonically with pressure, it seems either that gallium vacancies alone are important in the formation of dislocations or that the compound is arsenic rich near its melting point so that gallium vacancies predominate, as is known to be the case at 1,000° C where the solid extends from 49·998 to at least 50·009 atom per cent arsenic[9].

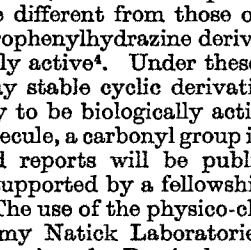
Chemical Nature of Free Retine, an Anti-tumour Agent

The wide distribution of natural anti-tumour agents has been shown by Szent-Gyorgyi *et al.*[1] and many others. There is, notably, such a compound in human urine, which has been called retine and has been previously isolated by Hegyeli *et al.*[2]. This compound has a molecular weight of approximately 430 (ref. 3) and induces a significant regression of Krebs-2 carcinoma in Swiss albino mice. Treatment of retine with hot acetic acid releases a compound which is responsible for the anti-tumour activity[4].

This small molecule, which will be called 'free retine' in this report, is soluble in organic solvents. The ultra-violet spectrum is characterized by a sharp absorption peak at approximately 275 mμ and by its absence of a *B* band. This feature makes it possible to rule out certain structures for free retine. For example, a diazine structure is not permitted, because the corresponding $n \rightarrow \pi^*$ transition generally occurs in the region 300–400 mμ[5]. The infra-red spectrum of free retine in chloroform solution is characterized by a strong band at 1,710 cm^{-1}, suggestive of a carbonyl group. It was thus tentatively assumed that this carbonyl group is a keto group, and a chloroform solution of free retine was treated at low *p*H by 2,4-dinitrophenyl-hydrazine (as suggested by Mr. John Sousa (U.S. Army Natick Laboratories)). Triclinic crystals (point-group I) were thus formed, the crystallographical description of which does not appear to have been published.

An infra-red spectrum of the derivative was recorded (micro-pellets in potassium bromide); it had the general aspect of the spectrum of 2,4-dinitrophenylhydrazine, although it differed significantly. A new band (*X*–*Y* stretch) appeared at 3,362 cm^{-1} and a very broad band at and below 1,645 cm^{-1} was suggestive of a non-ketonic carbonyl group.

The 2,4-dinitrophenylhydrazine derivative was dissolved in deuterated dimethyl sulphoxide and a nuclear magnetic resonance spectrum was recorded. In addition to the peaks of H_3, H_5 and H_6 of the substituent phenyl group, there also appeared an NH peak and a peak corresponding to two protons.



On the other hand, when a chloroformic solution of free retine is shaken with water, no biological activity[4] or any corresponding ultra-violet peak can be detected in the aqueous phase, whatever the *p*H. This rules out the possibility of a conventional ketone and of a keto-enol tautomerism because, at high *p*H, some of the material would dissolve in the water phase. The same is true of a quinone.

These findings were checked by spectroscopy, with the following results: (*a*) The band at 3,362 cm^{-1} which might have been due to a bonded OH does not appear with the 2,4-dinitrophenylhydrazine derivative of tetrahydroxy-1,4-quinone. (There is only a diffuse band centred on 3,420 cm^{-1}.) (*b*) The broad band at and below 1,645 cm^{-1} is not due to an amide group, as it does not appear with

the 2,4-dinitrophenylhydrazone of *o*-acetamide-acetophenone. (*c*) The broad band is not due to a C=N stretch of the addition compound of the reagent with a quinone, as it does not appear with the derivative of tetrahydroxy-1,4-quinone. (*d*) The derivative is not of the hydrazide type as, in that case, two different NH peaks would be distinguished by nuclear magnetic resonance.

In these conditions, the only remaining possibility is that the broad band is due to some other type of oxo-group. Free retine is, however, very volatile: if a chloroform solution of free retine is left at the air and room temperature, or if inert gases are bubbled through such a solution, all the activity disappears.

Therefore, the only compound with which free retine can be identified is carbon suboxide, for: (*a*) The two carbonyl groups are very reactive, as is always the case with ketenes. (*b*) It is a volatile compound (b. pt. 7° C (ref. 6)). (*c*) It is not soluble in water, but decomposes with formation of malonic acid. (*d*) It reacts with hydrazines[7]. With 2,4-dinitrophenylhydrazine it forms 1-(2,4-dinitrophenyl)-3,5-dioxopyrrazolidine:

a compound which obviously satisfies the spectroscopic (infra-red and nuclear magnetic resonance) observations.

It is of interest to recall that carbon suboxide undergoes photolytic reactions, reacts with proteins and that its toxic effects are different from those of malonic acid[8].

The 2,4-dinitrophenylhydrazine derivative of free retine is not biologically active[4]. Under these circumstances, it appears that any stable cyclic derivative of carbon suboxide is unlikely to be biologically active. It seems that in the retine molecule, a carbonyl group is readily available.

More detailed reports will be published later. This work has been supported by a fellowship of the Commonwealth Fund. The use of the physico-chemical equipment of the U.S. Army Natick Laboratories was invaluable, and samples were given by Dr. Andrew Hegyeli (Institute for Muscle Research).

Structure of a *bis*Glycylglycinate-cobalt(III) Complex

COBALT complexes of glycylglycine are of considerable importance in connexion with the activation of glycylglycine dipeptidase by cobalt ions[1]. Following early work by Smith[2], Gilbert, Otey and Price[3] studied the oxidation of cobaltous glycylglycine complexes and isolated a red complex to which the formula $[(GGH)_2CoO_2Co(GGH)_2]$ was assigned (the neutral glycylglycine molecule is abbreviated as GGH_2). Later studies[4] showed that an intermediate brown complex was formed at high *p*H which was converted to the red complex on lowering the *p*H. A polarographic study[5] found no evidence for a peroxy group in the red complex, it being suggested that the complex contained hydroxy groups as ligands.

We have, in attempting to prepare the red 'irreversible oxygen carrying' complex of Gilbert *et al.*, isolated a number of cobalt complexes with the unsubstituted glycylglycine and with its mono-anion $(GGH)^-$ and di-anion $(GG)^{2-}$. A single crystal X-ray diffraction analysis of the structure of $NH_4.[Co(GG)_2].2H_2O$ has now been completed, the stereochemistry of the complex anion being shown in Fig. 1. Corresponding to a present reliability index of 0·10, the average estimated standard deviations of the bond lengths are Co—N and Co—O 0·02 Å and C—N, C—O and C—C 0·03 Å.

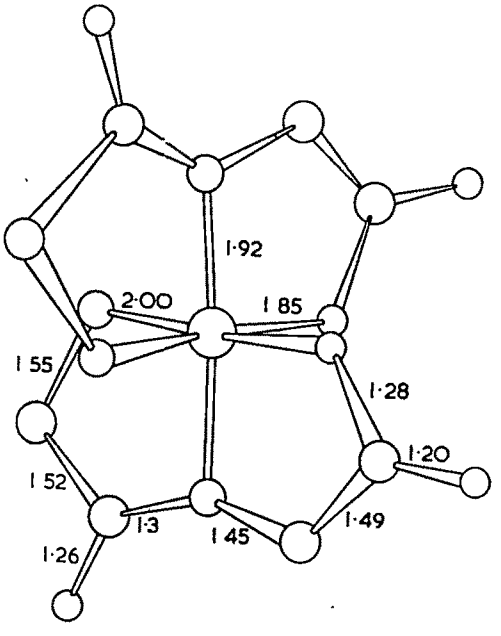

Fig. 1

The complex anion contains two terdentate glycylglycinate ligands arranged so that the co-ordination of the Co(III) ion is a distorted octahedron which has precise C_2 symmetry as a requirement of the crystallographic space group. The bond lengths in the co-ordinated ligands, which are not precisely planar, are very similar to those reported for copper(II) monoglycylglycine trihydrate[6] and β-glycylglycine[7]. As in the copper complex[6], the difference in the metal-nitrogen bond lengths, M—NH_2 and M—N, is significant.

The complex anions are extensively hydrogen bonded throughout the crystal to neighbouring ammonium ions and water molecules. Four N—H···O bonds of length 2·79 Å (twice) and 2·85 Å (twice) connect the ammonium ion with the unco-ordinated oxygens of the glycylglycinate ligand. The unco-ordinated carboxyl oxygen atom is also hydrogen bonded to a water molecule (O···O = 2·77 Å) which, in turn, is bonded to the co-ordinated oxygen (O···O = 2·80 Å) and to the terminal nitrogen atom (O···N = 3·06 Å).

Crystal structure analyses of several of the other complexes isolated are at present in progress. It seems possible that the mode of attachment of the ligand to the metal ion depends critically on the intermolecular hydrogen bonding. As yet, we have no evidence that the cobalt-glycylglycine system is different from that of the well-known cobaltammine complexes so far as the reaction with oxygen is concerned. The oxygen carrying complex appears to be the brown intermediate of Tanford *et al.*[4] which decomposes to a monomeric Co(III) complex.

We thank the Science Research Council for support of these and related studies.

Reactivity of Aromatic Compounds towards Hydrogen Atoms

The reactivity of aromatic compounds toward hydrated electrons and hydroxyl radicals has been the subject of various recent investigations[1,2]. The effects of substituents on the reactivities of benzene and benzoate ion were correlated with the substituent constant (σ) of Hammett's equation. It has been shown that the mechanism of attack of hydroxyl radicals on aromatic compounds is analogous to electrophilic aromatic substitution[2]. On the other hand, the reactions of hydrated electrons followed a pattern analogous to nucleophilic substitution. The reactivity of aromatic compounds toward hydrogen atoms was investigated in order to study the nature of the PhX + H reaction.

The specific rate constants of substituted benzenes with hydrogen atoms were determined by competition kinetics, using isopropanol as the competing compound. De-aerated solutions containing 5×10^{-2} M isopropanol, 1×10^{-3} M acetone (as e^-_{aq} scavenger in order to avoid the e^-_{aq} + PhX reactions) and different concentrations of PhX at *p*H 8–9, were irradiated in a cobalt-60 γ-source (4×10^{17} eV g^{-1} min^{-1}). The doses of irradiation were $8–40 \times 10^{17}$ eV g^{-1}. The yield of hydrogen was determined by gas chromatography (on a column of 'molecular sieves' 5 Å). Each experiment was repeated at least eight times and the coefficient of variation was ± 10 per cent.

Under the experimental conditions the hydrated electrons react with acetone, whereas the hydroxyl radicals react with isopropanol. Hydrogen atoms may react with isopropanol to form hydrogen, or with PhX to form PhXH radicals, which do not yield hydrogen[3]. The experimental yield of hydrogen is therefore the sum of the 'molecular' yield G_{H_2} and of G(H + isopropanol). G_{H_2} was determined under similar conditions using a solution of 1×10^{-3} M potassium bromide. The sum of G_H and G_{H_2} the total yield of hydrogen atoms, was determined using a solution of 5×10^{-2} M isopropanol + 1×10^{-3} M acetone. Using these values and the known value of the specific rate constant for the reaction of hydrogen atoms with isopropanol, $k_{H + isopropanol} = 5{\cdot}0 \times 10^7$ M^{-1} sec^{-1} (ref. 4), the rate constant of the reaction H + PhX was calculated:

$$k_{H + PhX} = \frac{k_{H + isopropanol} \cdot [G_H - G(H + isopropanol)]\,[isopropanol]}{G(H + isopropanol)[PhX]}$$

The results are summarized in Table 1. The order of reactivity is $PhSO_3^-$ < PhCN < $PhNHCOCH_3$ < $PhCH_2COO^-$ < $PhCOO^-$ < $PhCOCH_3$ < $PhNO_2$ < $PhNH_2$ < PhOH. This order is in fair agreement with the order of reactivity of these compounds toward electrophilic aromatic substitution, with one exception: the reactivity of nitrobenzene is much higher than would be expected from the general behaviour of aromatic substitution. This is most probably due to a direct attack by hydrogen atoms on the NO_2 group, as may be inferred from their fast reaction rates with NO_2^- ion[5,6] and $C(NO_2)_4$ (ref. 7).

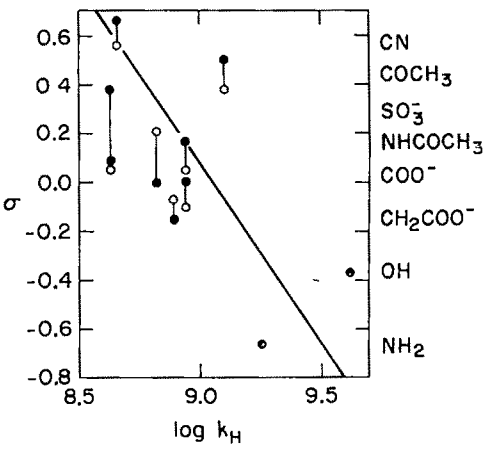

Fig. 1 Plot of log $k_{H + PhX}$ against σ

Table 1. Reactivity of Aromatic Compounds towards Hydrogen Atoms

Compound	Rate constant (M^{-1} sec^{-1})
$C_6H_5SO_3Na$	$4{\cdot}30 \times 10^8$
C_6H_5CN	$4{\cdot}53 \times 10^8$
$C_6H_5NHCOCH_3$	$6{\cdot}70 \times 10^8$
$C_6H_5CH_2COONa$	$7{\cdot}70 \times 10^8$
C_6H_5COONa	$8{\cdot}70 \times 10^8$
$C_6H_5COCH_3$	$1{\cdot}26 \times 10^9$
$C_6H_5NO_2$	$1{\cdot}66 \times 10^9$
$C_6H_5NH_2$	$1{\cdot}76 \times 10^9$
C_6H_5OH	$4{\cdot}20 \times 10^9$

A quantitative treatment of the results is shown in Fig. 1, where log $k_{H + PhX}$ is plotted against Hammett's σ values (taken from refs. 8 and 9). Both σ_m and σ_p values were taken for substituents having a deactivating effect, but only the σ_p values were taken for the other substituents. (The attack by hydrogen atoms on aromatic compounds is electrophilic in nature, thus their attack on the *meta* position of aromatic compounds carrying *ortho–para* directing substituents can be neglected.) A σ value similar to that of CH_2CH_3 and $CH_2CH_2COO^-$ groups was taken for the CH_2COO^- group. Neglecting the value for nitrobenzene, which is unexpectedly high, as explained before, a straight line could be drawn with a slope = − 0·7, which demonstrates the electrophilic nature of the attack of hydrogen atoms on aromatic compounds. The absolute value of ρ = − 0·7 is higher than that observed for the reaction of hydroxyl radicals (ρ = − 0·41) (ref. 2). This is in accordance with the relatively lower reactivity of hydrogen atoms, which makes them more selective.

The electrophilic behaviour of hydrogen atoms in the H + PhX reaction is not surprising, since a higher electron density on the aromatic ring promotes the formation of the new C—H bond and stabilizes the PhXH radical formed.

BIOCHEMISTRY

Activity of Lysosomal Enzymes in White Muscle Disease

DEFICIENCY of selenium and vitamin E in the diet of late-gestation ewes is known to cause white muscle disease (WMD) in lambs[1,2]. It is generally characterized by degenerative changes in skeletal and cardiac muscles. Since the myopathy is prenatally influenced, the development of the disease presumably has a direct relationship with the deprivation of protectors essential for the prevention of nutritional muscular dystrophy.

Lysosomes, a group of sub-cellular particles rich in a variety of acid hydrolases, have already been shown to occur in the dystrophic tissues of vitamin E-deficient rabbits[3] and chicks[4] and in the genetic dystrophy of mice and chickens[5]. Since white muscle disease is a degenerative disease of nutritional origin, I set out to investigate its lysosomal activity so as to make possible a comparison between the biochemical lesions of this disease and those observed in the dystrophies of other species. This report concerns the activities of five typical lysosomal enzymes in the muscle tissues of normal and dystrophic white muscle disease lambs.

Lambs, 4–6 weeks old and showing distinct symptoms of leg weakness were killed and the dystrophic tissues from leg muscles were collected and immediately frozen. Equivalent tissue samples were also collected from normal lambs of similar age. For chemical analysis, a 10 per cent tissue homogenate was made in ice-cold, de-ionized water by mincing the tissue in a Servall 'Omnimixer' for 1 min.

The activity of individual lysosomal enzymes was determined by several assays as follows. Acid phosphatase, β-glucuronidase and cathepsin were determined by the methods of Gianetto and de Duve[6]. β-Galactosidase was assayed by the method of Sellinger *et al.*[7]. Aryl sulphatase was assayed by the method of Roy[8] with 2-hydroxy-5-nitrophenyl sulphate as substrate. The specific activities of the enzymes are expressed in mμmoles substrate hydrolysed/mg nitrogen/min.

Table 1. LYSOSOMAL ENZYMES IN LEG MUSCLE OF NORMAL AND DYSTROPHIC WMD LAMBS

Enzyme	Specific activity* Control	Dystrophic WMD	Increase in lysosomal activity over control
Aryl sulphatase	0·16	5·63	35 ×
β-Glucuronidase	3·01	15·18	5 ×
β-Galactosidase	0·64	1·80	3 ×
Cathepsin	0·14	0·44	3 ×
Acid phosphatase	4·64	9·98	2 ×

* Expressed as mμmoles of substrate hydrolysed per mg nitrogen per min. Values represent average of two lambs in each group.

The specific activities of five typical lysosomal enzymes in muscle tissues of normal and dystrophic white muscle disease lambs are presented in Table 1. The activity of individual lysosomal enzymes in dystrophic tissues was greater than in the controls, and the increases were as follows: aryl sulphatase, 35-fold; β-glucuronidase, 5-fold; β-galactosidase and cathepsin, 3-fold; acid phosphatase, 2-fold. These ratios are similar in magnitude to those observed in dystrophic muscle tissues of vitamin E, selenium and sulphur amino-acid-deficient chicks[4] and vitamin E-deficient rabbits[3]. Increased 5-nucleotidase activity in white muscle disease of lambs[5] may also be associated with the lysosomal complex.

It appears from all these observations that the phenomenon of increased lysosomal activity is directly associated with degradative changes occurring in tissues undergoing dystrophy. A recent time-sequence study[10] of the appearance of nutritional muscular dystrophy in chicks indicated that initiation of the primary damage is usually caused by the deficiency of the tissue protectors and that the activities of the lysosomal enzymes increase as a result of the infiltration of macrophages, the carriers of lysosomes. Although lysosomes may not be the primary initiators of the tissue damage, the greatest part of the hydrolytic breakdown in a tissue undergoing dystrophy is the result of large increases in free and total activities of various lysosomal hydrolases. Recent studies showed that isolated lysosomes are fully capable of digesting most cellular constituents[11]. The triggering mechanism responsible for the involvement of lysosomes in muscular dystrophy still remains obscure.

I thank Dr. D. E. Hogue for providing sheep tissues and Dr. M. L. Scott for providing research facilities.

Abnormal Isoenzyme Patterns in Human Myopathies

PROTEINS may exist in different molecular forms possessing the same enzymatic activity and which have been called isoenzymes[1] or isozymes[2]. Lactate dehydrogenase has been extensively studied and appears to consist of five isoenzymes, each of which is a tetrameric association of two sub-units, *M* and *H*. It has been shown that the synthesis of either sub-unit may be altered in response to hormonal, environmental or neural changes[3]. Evidence has also been presented which suggests that the synthesis of the two sub-units is controlled by two separate genes[4].

In normal adult human skeletal muscle, the slowest isoenzyme, LDH-5, predominates[5–7]. (By convention[1], the isoenzyme having the highest mobility towards the anode is numbered 1.) In normal foetal skeletal muscle, LDH-5 possesses little or no activity[8,9]. Recently, Emery reported that LDH-5 is also absent in skeletal muscle from victims of Duchenne muscular dystrophy[8], but this gross aberration has not been found in all cases of Duchenne dystrophy[10].

The isoenzyme patterns of NADP-linked isocitrate dehydrogenase (ICDH), malate dehydrogenase (MDH) as well as lactate dehydrogenase (LDH) were investigated electrophoretically in human myopathies to see if any alterations were specific for one disease.

Biopsy samples were removed from the gastrocnemius muscle, cooled in ice and processed immediately. The specimens were dropped in 0·25 M sucrose and blotted to remove blood. A 100-mg sample of tissue was then homogenized briefly in a small glass tissue grinder. Then 0·2 ml. of distilled water were added and the homogenization was continued. The whole procedure was performed in an ice-bath and the homogenization was discontinued frequently to prevent the accumulation of heat. The time occupied in homogenization was 2 min. The homogenate was transferred to a micro-centrifuge tube and was frozen and thawed once, after which it was centrifuged at 20,000*g* and 0° C for 15 min. The resultant supernatant

liquid was applied directly to the gel so as to localize MDH and ICDH. A portion of the supernatant was diluted with four volumes of distilled water and applied to the gel for LDH localization. Vertical starch-gel electrophoresis was used with the *p*H 7·0 phosphate–citrate buffer system of Fine and Costello[12]. A potential gradient of 4 V/cm was applied to the gel for 18 h at 4° C. The enzymes were made visible by the methods of Fine and Costello[12].

In all the cases tested, MDH was normal. There were no alterations among the six isoenzymes of MDH which are found in normal human muscle[13]. This agrees with the preliminary findings of Pearson[10] for the Duchenne cases.

In two cases of Duchenne dystrophy, both LDH and ICDH patterns were normal. In two other cases of Duchenne, LDH-5 was absent. One of these cases also exhibited an absence of ICDH-2. The other sample provided insufficient material to allow for ICDH detection. (In normal skeletal muscle there are three isoenzymes of ICDH, ref. 13.) In three other cases of the same disease, there was a decrease in the activity of LDH-5 and an increase in activity of the rapid isoenzymes. Two of these three cases also lacked ICDH-2.

In two cases of Werdnig–Hoffmann muscular atrophy, LDH-5 was extremely weak and LDH-1 was more active than LDH-5. From one sample there was again sufficient supernatant to show that ICDH-2 was absent. In one case of possible amyotonia congenita, LDH-5 was very weak and ICDH-2 was absent. The gels for this case are shown in Fig. 1. In one case of possible myotonia congenita, both LDH and ICDH were normal.

It has already been proved[13] that ICDH-2 is the most labile isoenzyme of ICDH. Exposure of normal skeletal muscle autopsy material to room temperature for several hours brings about a decreased activity of ICDH-2. However, exposure of liver samples to room temperature results in a complete loss of the same isoenzyme. Hence the loss of the liver isoenzyme may possibly be explained on the basis of an attack by proteolytic enzymes which are present in the liver.

Similarly, one can postulate the presence of an abnormal amount of catheptic activity in certain pathological muscles to account for the absence of ICDH-2. Indeed, there have been reports of increased catheptic activity in human Duchenne muscular dystrophy[14], hereditary mouse muscular dystrophy[15,16] and in experimental denervation[17]. Denervation also brings about a loss in LDH-5 in rabbit muscle[3]. The alterations in isoenzyme patterns may, on the other hand, reflect a delayed maturation of the enzymes in skeletal muscle[18].

From the results of this brief survey, it is evident that alterations in the isoenzyme patterns of LDH and ICDH occur in several myopathic conditions. Further investigation is required to determine whether or not these findings are of possible diagnostic or aetiological value.

Dr. E. G. Murphy and Dr. M. W. Thompson of the Toronto Hospital for Sick Children provided the diagnoses and biopsy samples for this study. This research was supported by a grant from the Muscular Dystrophy Association of Canada.

Limitations on the Use of the Concept of Quantum Efficiency in Rhodopsin Bleaching

The purpose of this communication is to discuss the extent to which the concept of quantum efficiency can be applied to the bleaching of rhodopsin. Quantum efficiency of bleaching, γ, is defined by:

$$\gamma = \left(\frac{\text{No. of molecules bleached}}{\text{No. of quanta absorbed}}\right)$$

By making use of this definition and by careful consideration of both theoretical and experimental contingencies, Dartnall, Goodeve and Lythgoe[1] concluded that $\gamma = 1{\cdot}0$ (or not much less) when fairly dim, visible light was used for bleaching. This conclusion remained virtually unquestioned until Hagins[2] reported the observation that, no matter how high its intensity was made, a short (less than about 1 msec) flash would not bleach more than about 50 per cent of the rhodopsin present. Because of this result, the idea was unfortunately introduced that γ at high intensities had a limiting value of 0·5.

At first, these two results appeared to contradict each other. How can $\gamma = 1{\cdot}0$ when the upper limit on bleaching is 50 per cent? Hubbard and Kropf[3] were among the first to suggest that the two results were not mutually exclusive. They were investigating the quantum efficiencies with which various species involved in bleaching are interconverted by light. One of these conclusions was that the quantum efficiency of bleaching is not constant but depends on both intensity and temperature.

I investigated the effect of one of these parameters, intensity, on the extent of bleaching with short duration flashes[4]. It was found that, while $\gamma = 1{\cdot}0$ for low intensities, there was a systematic decline in the efficiency of bleaching as the intensity was increased. The maximum extent of bleaching in those experiments probably was about 50 per cent. Care was taken, at that time, not to confuse the maximum extent of bleaching with the upper limit of γ. Failure to clearly distinguish between these two has caused[2], and is at present causing[5], confusion.

The high-intensity limit on γ is zero; it is not 0·5. This is readily shown with two examples. (1) In low temperature experiments, where bleaching is arrested at one stage or another, long-term irradiation results in only a 50 per cent bleach on warming, even though each molecule may have absorbed many quanta. In the limit as irradiation time goes to infinity, each molecule absorbs an infinite number of quanta and still only 50 per cent of them bleach. Hence, in this case, $\gamma = 0{\cdot}5 \times$ (No. of molecules present)$/\infty = 0{\cdot}0$. (2) The same situation as in (1) obtains if, instead of using low temperatures to prevent actual bleaching during the irradiation time, one uses very short duration flashes. (This is discussed thoroughly in refs. 3 and 4). In this case, if a short flash of (hypothetically) infinite intensity is given, no more than 50 per cent bleaching occurs even though an infinite number of quanta were absorbed. Again, $\gamma = 0{\cdot}0$.

Experimentally, of course, γ never reaches a zero value. Theoretically, however, the foregoing arguments show that it can take on any value between 1 and zero. This fact, it seems, seriously limits the usefulness of the concept of quantum efficiency as applied to bleaching. In short, without an independent measure of the number of quanta actually absorbed (say, by actinometry), only the use of very low intensities makes it possible to invoke a particular value of γ (namely, 1·0) in order to explain experimental results.

Detection of Cholinesterase-inhibiting Insecticide Chemicals and Pharmaceutical Alkaloids on Thin-layer Chromatograms

This communication reports a sensitive and rapid method for detecting cholinesterase (ChE) inhibitors, such as certain phosphate and carbamate insecticides and pharmaceutical alkaloids utilizing a direct assay on thin-layer chromatography plates coated with cellulose and developed in a reverse phase solvent system.

Recently, Bunyan[1] described a sensitive indirect detection method for organophosphorus insecticides based on ChE inhibition on thin-layer chromatography plates coated with silica gel *H*. Spots of inhibitory compounds were transferred by contact from the developed thin-layer chromatography plates to 3-mm Whatman paper which was pre-treated with human plasma as the source of ChE. Subsequent treatment of the paper with acetylcholine (ACh) and indicator gave spots corresponding to inhibitors. Attempts to detect inhibitors directly on thin-layer chromatography plates were unsuccessful. Crosby *et al.*[2] reported a similar thin-layer chromatography procedure for detection of a number of carbamate insecticides using plates coated with aluminium oxide *G*; after development the chromatograms were sprayed with the plasma-indicator solution and spots corresponding to inhibitors were shown on a filter paper sheet soaked in ACh solution by placing the latter in contact with the thin-layer chromatography plate.

In the present investigation, thin-layer chromatography plates, 20 × 20 cm, coated with 1·0 mm '*MN*-cellulose powder 300 *G*' (Macherey, Nagel and Co., Düren, Germany) were used. The adsorbent slurry of 86 g cellulose and 435 ml. water (ratio 1 : 5) was adjusted to *p*H 11 with aqueous dilute sodium hydroxide solution, applied to the plates with a Brinkman–Desaga applicator and air-dried overnight. The dried plates were coated by dipping with a stationary phase consisting of a 5 per cent v/v solution of Dow Corning 'Silicone 555' fluid in acetone and the carrier solvent was evaporated. Acetone, methanol or water solutions of analytical grade insecticide chemicals and pharmaceutical alkaloids were spotted in 2-μl. volumes 2·0 cm above the lower edge of the plates. Development was accomplished with a mixture of water, absolute ethanol and chloroform (56 : 42 : 2). This reverse phase solvent system was similar to that used by Hopkins[3] for paper chromatograms. Cook's method[4] as modified by Getz and Friedman[5] for detection of ChE-inhibiting spots on paper chromatograms was adapted to thin-layer chromatography plates. The plates were sprayed with human blood plasma (undiluted, pooled, outdated) as the ChE source. After incubation for 0·5 h at room temperature, the plates were dried and liberally sprayed with a freshly prepared substrate indicator solution consisting of 1 part of 0·6 per cent bromthymol blue in 0·1 normal sodium hydroxide and 15 parts of 1 per cent ACh chloride in water. Inhibiting substances appeared as intense blue spots against a yellow background. Maximum definition of the spots usually resulted when the thin-layer chromatography plates were lightly resprayed several times with the substrate indicator solution. These spots faded within 30 min to several hours after development; however, by sacrificing some sensitivity, it was possible to redevelop partially faded spots after a longer interval by respraying the plates with substrate indicator solution. Attempts to detect spots by this direct enzyme inhibition method on thin-layer chromatography plates coated with silica gel and 'Florisil' were unsuccessful. The insecticides and alkaloids included in this investigation are listed in Table 1 with their respective R_P values and limits of detection as distinct blue spots on a yellow background. The procedure proved to be highly sensitive for detection of various phosphate and phosphorothiolate esters where in several instances ChE-inhibition was evident for amounts in the nanogram range or less. The streaking associated with 'Zectran' was probably due to a number of inhibitory compounds. Crosby *et al.*[2] reported that an analytical sample of 'Zectran' contained two major ChE inhibitors and one minor ChE inhibitor.

The ChE inhibition detection procedure was also very sensitive for a number of pharmaceutical alkaloids (kindly presented by Dr. Werner Deckers, C. H. Boehringer Sohn, Ingelheim am Rhein, West Germany). The alkaloids for which the greatest sensitivity was noted are given in Table 1. Several additional alkaloids were detected at a 20-μg level: ajmaline, arecoline hydrobromide, atropine methylbromide, emetine hydrochloride, hyoscyamine hydrobromide, and yohimbine hydrochloride. The following alkaloids gave no detectable spots with 20 μg: atropine sulphate, scopolamine methylbromide and rescinnamine. Solanine and its aglucon derivative, solanidine (both obtained from K and K Labs., Plainview, N.Y.), gave two inhibition zones on the thin-layer chromatography plates. By using a similar procedure on paper chromatograms, solanidine is resolved into at least five inhibitory spots and solanine into a single spot[6].

The described procedure appears to be an improvement over previous methods for rapid qualitative determination of trace amounts of ChE-inhibiting chemicals. It may be

A Factor inhibiting the Adenosine Triphosphatase Activity and the Superprecipitation of Actomyosin

Ebashi[1] has produced evidence for a protein factor in the presence of which the magnesium-activated ATPase[2] and the superprecipitation[1] of actomyosin are inhibited by low concentrations of ethylene *bis*(NN′diacetyl β amino ethyl) ether (EGTA). To observe the effect of this factor the actomyosin was prepared from separately purified actin and myosin, so-called 'synthetic' actomyosin. We have obtained similar effects with an actomyosin preparation extracted as the complex from muscle and treated by a procedure described elsewhere[3]. This preparation is referred to in this communication as desensitized actomyosin.

During the course of investigations[3] on the EGTA-sensitizing factor, it was noted that in some circumstances an apparently different preparation was obtained which inhibited the magnesium-activated ATPase of actomyosin in the absence of EGTA. There was also some evidence that the amount of the inhibitory factor increased as EGTA-sensitizing factor preparations aged. Active inhibitor preparations were consistently prepared from rabbit skeletal muscle by the following procedure. A crude concentrated myofibril suspension (prepared essentially as described by Perry and Zydowo[4]) was extracted with an equal volume of a solution containing 1·2 M potassium chloride, 0·08 M sodium bicarbonate and 0·02 M sodium carbonate, the whole extract allowed to stand for 15 h at 0° C and then dialysed extensively against 40 mM potassium chloride, 6·7 mM phosphate buffer, *p*H 7·2. After the precipitate had been centrifuged down, the supernatant was filtered and freeze-dried. The factor was further purified from the freeze-dried protein by precipitation at 0° C by the addition of ammonium sulphate to 30 per cent saturation. When this preparation was added to 'desensitized' actomyosin marked inhibition of the magnesium ATPase occurred (see Fig. 1). Inhibition of the magnesium activation of the ATPase of 'synthetic' actomyosin was also obtained, but 'natural' actomyosin containing EGTA-sensitizing factor and myofibrils were less sensitive to the inhibitor. Little inhibition was obtained with desensitized actomyosin when calcium was the activating divalent cation (Fig. 1). The factor also inhibited the superprecipitation of desensitized actomyosin (Fig. 2).

The fact that the inhibitor was precipitated by ammonium sulphate, destroyed by trypsin and heat, and that it lost activity on prolonged storage at 0° C suggests that it is protein in nature. Studies on the turbid supernatant obtained after myofibrils were removed from muscle homogenates in 0·025 potassium chloride, 0·039 borate, *p*H 7·0, showed that inhibitory factor could be prepared neither from the reticular-granular fraction sedimented after 1 h at 100,000*g* nor from the soluble sarcoplasm. This suggests that the inhibitory factor is localized in the

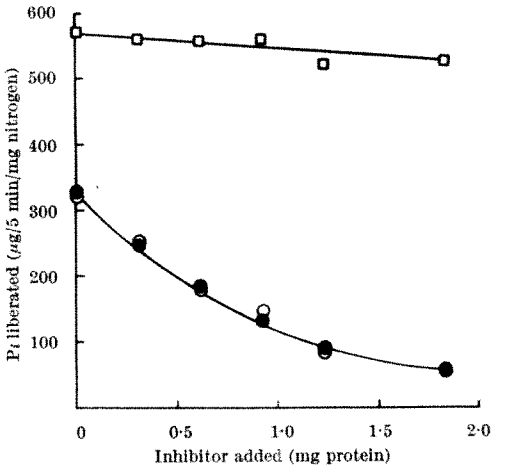

Fig. 1. Effect of inhibitor on the calcium and magnesium activated ATPase of desensitized actomyosin. The assay was carried out by incubating for 5 min at 25° C in 2 ml. containing 25 mM *tris*-HCl, *p*H 7·6, 2·5 mM *tris*-ATP and the following additions: ○, 2·5 mM magnesium chloride and 1·24 mg actomyosin; ●, 2·5 mM magnesium chloride, 1·24 mg actomyosin and 1 mM EGTA; □, 2·5 mM calcium chloride and 0·83 mg actomyosin

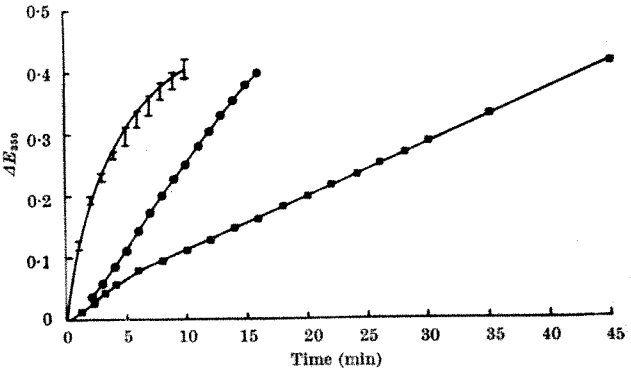

Fig. 2. Superprecipitation of desensitized actomyosin preparations in the presence of inhibitory factor. Superprecipitation followed by measurement of E_{350} at 25° C. Conditions: 25 mM *tris*-HCl, *p*H 7·6, 2·5 mM magnesium chloride 35 mM potassium chloride and 1·24 mg actomyosin; reaction started by addition of *tris*-ATP to 2·5 mM in a total vol. of 3 ml. at zero time. ——, Control, no further addition; ●, 0·61 mg inhibitor preparation added; ■, 1·83 mg inhibitor preparation added

myofibrils or associated with some component not readily removed from them by repeated washing and centrifugation.

The most active inhibitor preparations usually contained less than 1 per cent of tropomyosin when assayed by the method described by Perry and Corsi[5]. This fact coupled with its solubility characteristics indicated that the factor was neither 'natural' nor Bailey[6]-type tropomyosin[7]. Preparations which inhibited the magnesium-activated ATPase of desensitized actomyosin could not be obtained from actin by the procedure outlined here. The inhibitory factor does not seem to be identical with α-actinin which has the opposite effect on the superprecipitation of actomyosin gels[8].

The precise role of this inhibitor is not yet clear, but in so far as it inhibits the ATPase activity and superprecipitation of actomyosin it has the characteristics previously ascribed to relaxing factors. The best preparations obtained so far are not homogeneous but contain little or no EGTA-sensitizing factor activity (Fig. 1). Nevertheless it is possible that the inhibitor is a modified form of the EGTA-sensitizing factor, and investigations are now in progress to decide whether such a relationship exists.

Higher Glucose Affinity of Hexokinase in Sheep Brain than in Rat Brain

The brain in sheep, as in non-ruminant mammals' appears dependent on glucose as the substrate for oxidation[1], yet the blood glucose concentration of adult sheep is only about 2·5 mM (50 mg/100 ml.) compared with about 5 mM (100 mg/100 ml.) in rats, dogs, men and pigs. If the availability of a substrate is less in one species than in another, and a tissue were to utilize the substrate at comparable rates in both species, then one might look for an inter-species difference in enzyme affinity for this substrate. So we have estimated the apparent *Km* for glucose of hexokinase in brain, also liver, muscle and adiposa, of sheep and rats.

The rats were killed by decapitation and the sheep by electrocution. Our procedures for the preparation of homogenate supernatants and for estimating glucokinase activity by NADPH generation in the presence of added ATP, Mg^{++} and glucose-6-phosphate dehydrogenase have been described previously[2], except that a single glucose concentration of 1 mM was used before, while a series, usually of twelve points between 0·002 and 150 mM, was used in the present investigations. Some supernatants were used immediately, and others were dialysed for 20 h. Ammonium sulphate fractions were prepared from brain and liver of three sheep and three rats; in these experiments the series of glucose concentrations was limited to four or five points. Double reciprocal plots were made (for example, Fig. 1), and the apparent *Km* was calculated as the reciprocal of $-1/S$ when $1/V = 0$.

In liver, muscle and adiposa, the apparent *Km* of hexokinase for glucose was about the same in the sheep as in the rats (Table 1). Our rat data agree with those of previous authors[3]. A second hexokinase of rat liver, often called 'glucokinase', which has a *Km* of about 11 mM (Table 1), was absent from sheep liver. This was previously reported by Ballard and Oliver[4]. In sheep brain, the apparent *Km* of hexokinase for glucose was about half that of rat brain (Table 1): this difference was statistically significant. This difference should persist through purification procedures if it lies in the enzyme proteins, but not if it is due to accessory factors which may affect the apparent *Km*. A two-fold increase in specific activity was achieved by ammonium sulphate fractionation (Table 2): the rat brain glucokinase activity was maximal in the 30–50 per cent fraction, while the sheep brain glucokinase activity was maximal in the 50–75 per cent fraction (Table 2). Moreover, the apparent *Km* was about the same in the dialysed supernatants and corresponding ammonium sulphate fractions (Fig. 1). These two observations suggest that, compared with rat brain, the hexokinase of sheep brain is a larger protein with a greater affinity for glucose.

Any physiological significance of the data presupposes that the availability of glucose at the site of glucokinase activity inside cells is at least in part dependent on the

Table 1. Apparent *Km* of Hexokinases from Sheep and Rat Tissues*

		Mean (mM)	Maximum (mM)	Minimum (mM)	No. of observations
Liver	Rat	0·012	0·017	0·006	5
	Sheep	0·012	0·017	0·008	5
	Rat	11·0	12·5	9·5	4
Muscle	Rat	0·093	0·143	0·060	6
	Sheep	0·090	0·140	0·035	5
Fat	Rat	0·089	0·113	0·075	4
	Sheep	0·078	0·091	0·068	4
Brain	Rat	0·054†	0·086	0·040	7
	Sheep	0·020†	0·033	0·011	8

* Each *Km* was determined from the double reciprocal plot of rates of the reaction varying with glucose concentrations from 0·002 mM to 150 mM. Other final concentrations in the reaction mixture were 50 mM glycylglycine at *p*H 7·6, 8 mM magnesium chloride, 3·0 mM adenosine triphosphate (except in the blanks), 0·25 mM NADP, 2 mM EDTA, and each cell contained at least 0·02 Kornberg units of glucose-6-phosphate dehydrogenase activity.
† $t = 4{\cdot}536$, $P < 0{\cdot}001$.

Table 2. Glucokinase Activities of Ammonium Sulphate Precipitated Fractions of Rat and Sheep Brain

Fraction	Activity (units/g protein)* Rat	Sheep
100,000*g* supernatant	37·2	19·0
0–30 per cent ammonium sulphate	27·0	7·5
30–50 per cent ammonium sulphate	71·8	16·4
50–75 per cent ammonium sulphate	35·6	40·5

* 1×10^{-6} moles of NADPH generated/min/g biuret protein under the reaction conditions described in Table 1, except that only 1 mM glucose was used.

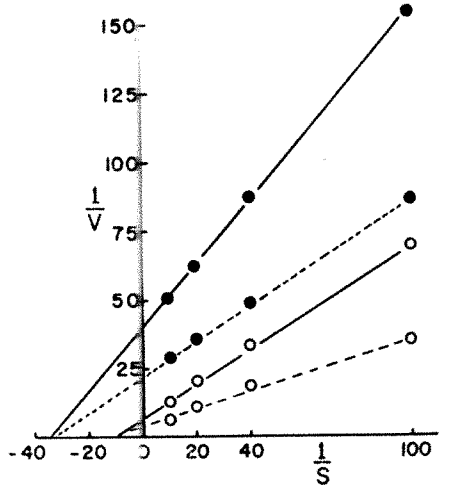

Fig. 1. Double reciprocal plots of the rate of glucokinase activity, *V*, against glucose concentration, *S*, show that the apparent *Km* for glucose (the reciprocal of $-1/S$) of a homogenate supernatant from sheep brain (plotted as ●) differs from that of rat brain (○), and that these values are unchanged by a two-fold purification. The hexokinase was concentrated in the 30–50 per cent ammonium sulphate precipitated fraction of rat brain (dashed line) but in the 50–75 per cent fraction of sheep brain (dotted line)

blood glucose concentration, which is much lower in adult sheep than in most monogastric mammals. It is a striking coincidence that the hexokinases of tissues which can utilize substrates additional to glucose, that is liver, muscle and adiposa, have the same glucose affinities in rats and sheep, while the tissue which is dependent on glucose as the substrate for oxidation, that is the brain, has a hexokinase with a higher affinity for glucose in the sheep than in the rat. The high affinity of sheep brain hexokinase for glucose offers a biochemical explanation of how sheep brain functions normally for years at a blood glucose concentration of 50 mg/100 ml. which would lead to hypoglycaemic manifestations in most mammalian species.

An exaggeration of this situation is found during insulin-induced hypoglycaemia. Men and rats exhibit tremors, convulsions and coma within 1–4 h when the blood glucose concentration falls to less than 50 mg/100 ml. (refs. 5–7). In contrast, sheep exhibit no ill effects in association with blood glucose-levels about 10 mg/100 ml. for 15 h or more[8–10]. This 'insulin resistance' has been attributed to the release of endogenous epinephrine, which is thought to cause cerebral vasodilatation and so sustain cerebral perfusion with glucose despite the hypoglycaemia[9,10]. It seems likely that the high affinity of its hexokinase for glucose would also contribute to the ability of the sheep brain to resist the ill effects of severe hypoglycaemia.

We thank Dr. R. E. Davies, chairman of our Department, and Dr. S. Weinhouse of Temple University for advice. The work was supported by the U.S. Public Health Service.

Encephalitogenic Peptides from Spinal Cord

In a recent symposium on experimental allergic encephalomyelitis there was considerable discussion on the size of encephalitogenic factors from brain and spinal cord[1–4]. We have fractionated extracts from bovine spinal cord by gel-filtration with phenol–acetic acid–water. This solvent system was introduced by Synge and colleagues[5–7] for the fractionation of peptides on 'Sephadex *G*-75'. It is a strongly dissociating solvent which prevents adsorption of peptides on 'Sephadex', and gel-filtration in this solvent can be used to estimate the molecular size of peptides as there is an approximately linear relationship between the relative elution volume and the log of molecular weight[8,9]. This communication describes a typical fractionation of basic polypeptides which were found to produce experimental allergic encephalomyelitis in guinea-pigs.

For the fractionation shown in Fig. 1, 'Sephadex *G*-75' (crushed type, fine) (Pharmacia, Uppsala) was allowed to swell for 2 days in phenol–acetic acid–water, 1 : 1 : 1 (w/v/v). 'Sephadex *G*-75' swells less in this solvent than in water, so that a settled bed of 9·9 ml./g was obtained. An acetone-dried powder of bovine spinal cord was extracted at 4° C with 0·01 N hydrochloric acid (100 g/l.) for 2·5 h. The filtered extract was lyophilized to yield 3·24 g (0·7 per cent of fresh cord). The re-dissolved extract was dialysed against water in acetylated cellulose tubing (18/32 'Visking')[10] for 30 h with four changes of diffusate. The retentate was lyophilized and any acidic material present was removed by passing it through diethylaminoethyl 'Sephadex *A*-50' in pyridine, 1 per cent: collidine, 1 per cent, titrated with acetic acid to *p*H 7·5. The basic fraction from the column was collected and represented 0·12 per cent of fresh cord. A portion of this material (100 mg) was fractionated on a 3 g column of 'Sephadex *G*-75' with phenol–acetic acid–water as solvent. The fractions were examined by paper chromatography in *n*-butanol–acetic acid–water (4 : 1 : 5) and by electrophoresis in acrylamide gel[11] with formic acid–acetic acid–water (1 : 4 : 45 by volume) containing 4 M urea, as buffer. The elution weights of the fractions with encephalitogenic activity, 1*B* and 1*C* (Fig. 1), were between that of glucagon and bacitracin which should indicate a molecular weight between 3,500 and 1,500. Paper chromatography showed that fractions 1*D* and 1*E* were composed mainly of free amino-acids. Gel-electrophoresis showed in the starting material eight cationic bands (Fig. 1). The slowest bands were found in fraction 1*A*. Encephalitogenic activity was found to be associated with fractions which contained the electrophoretic bands '*g*' and '*f*'. Table 1 shows the recovery of dry matter and the encephalitogenic activity of the fractions. A portion of fraction 1*C* was rechromatographed on the same column. The fractions equivalent to 1*B* were found to be encephalitogenic at a dose of 5 μg.

In other gel-filtration experiments carried out on material prepared from bovine spinal cord by extraction with acidified potassium chloride followed by precipitation with saturated ammonium sulphate, and previously referred to as 'basic protein fraction'[1–4,12], it was found that about half this fraction could be recovered from a 'Sephadex *G*-75' column with phenol–acetic acid–water as solvent in a zone equivalent to a molecular weight of 1,500–2,000. Maximum encephalitogenic activity, as judged by the number of animals showing clinical and histological symptoms and by the day of onset of the disease, was consistently found to be associated with the fractions showing bands with electrophoretic mobility

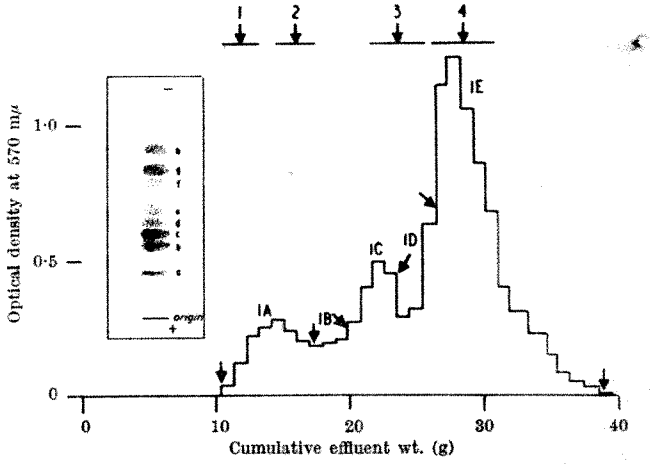

Fig. 1. Separation of basic fraction (100 mg) from bovine spinal cord on a 3 g column of 'Sephadex *G*-75' (crushed type) with phenol–acetic acid–water (1 : 1 : 1 w/v/v) as solvent. Fractions pooled for lyophilization are shown between the arrows. Arrows at the top of the graph show the peaks of reference compounds, bars indicate the limits of these zones. (1) Cytochrome *c*, molecular weight 12,400; (2) glucagon, 3,485; (3) bacitracins, 1,400–1,500; (4) free amino-acids. Inset shows acrylamide gel-electrophoresis of starting material, in formic acid–acetic acid–water (1 : 4 : 45 by volume) *p*H 2·0 containing 4 M urea

Table 1. Separation of Basic Fraction from Spinal Cord by Gel-filtration

Fraction	Dry matter recovered	Dose used (μg)	Encephalitogenic activity* Incidence (clinically positive)	Day of onset Range	Day of onset Mean	Histology positive
1A	20·4	50	0/5	—	—	1/4
1B	9·6	100	3/5	11–17	13·7	3/5
1C	21·6	100	3/5	11–13	11·7	4/5
1D	11·3	—	—	—	—	—
1E	37·8	100	0/5	—	—	0/5

* Encephalitogenic activity was determined, in guinea-pigs, by a single intradermal injection (0·1 ml.) of the test material, at the dose shown, dissolved in sterile saline and emulsified with an equal volume of 'complete Freund's adjuvants' composed of 'Bayol F', 85 parts, and 'Ariacel A', 15 parts, with added heat-killed *Mycobacterium tuberculosis* to the final amount of 0·25 mg bacillary powder per animal (see ref. 12).

Table 2. Amino-acid Composition of an Encephalitogenic Fraction from Bovine Spinal Cord

Amino-acid	Moles/100 moles amino-acid	Amino-acid	Moles/100 moles amino-acid
Lysine	9·3	Half cystine	0·0
Histidine	4·7	Valine	1·6
Arginine	6·7	Methionine	0·4
Aspartic acid	5·3	Isoleucine	1·7
Threonine	5·0	Tyrosine	2·7
Serine	10·5	Phenylalanine	3·6
Glutamic acid	7·3	Unknown 1	0·2
Proline	8·3	Unknown 2	0·3
Glycine	18·1	Ammonia	6·1
Alanine	8·1		

Sample was hydrolysed with 6 N hydrochloric acid for 22 h at 110° C. Amino-acids were determined on a Spinco model 120*B* amino-acid analyser by Dr. C. M. Mauritzen. Serine and threonine have been corrected for 10 per cent destruction. Unknown 1 was just before arginine and unknown 2 was just before aspartic acid.

equivalent to bands '*g*' and '*f*' and with an elution weight equivalent to that of a peptide with a molecular weight of about 3,000.

In Table 2 is given the amino-acid composition of an encephalitogenic fraction obtained from the 'basic protein fraction'. The amino-acid composition is unusual in its high content of glycine, serine and basic amino-acids. This amino-acid composition is similar to those of the preparations analysed by Kies[14] and by Caspary and Field[3] and, apart from these materials, the only group of proteins of remotely similar composition is a recently reported histone-like protein isolated by Hnilica[15] from thymus gland and named by him a 'lipohistone'. Our fraction obtained from the 'basic protein fraction' was eluted from a column in a position equivalent to the tail of the chymotryptic haemo-peptide (molecular weight 3,439) from a digest of cytochrome *c* (ref. 13). High-voltage gel-electrophoresis showed that it was composed of at least three peptides of cationic mobility similar to bands '*e*', '*f*' and '*g*' in Fig. 1. The minimum effective dose of this material was 2 μg per guinea-pig. The mild and rapid procedure used to obtain fractions 1*B* and 1*C* suggests that the encephalitogenic peptide(s) occurs naturally in spinal cord and that it is (or they are) not derived from proteins during the fractionation. In this latter connexion, it is to be said that phenol–acetic acid–water was found by Bagdasarian *et al.*[6] to produce no significant hydrolysis of peptides at room temperature and that we ourselves found that there was no liberation of peptides or amino-acids from cytochrome *c* kept in this solvent for 5 months at 4° C. It is probable, from the work of Kies and others[16–20], that they are loosely bound in some way to the lipid components of myelin. Evidence is accumulating that the encephalitogenic factor from spinal cord is a polypeptide which is free to diffuse through 'Cellophane'[1–4,21,22]. Recently, Nakao and Roboz-Einstein[23] briefly reported that there were two encephalitogenic factors in extracts of spinal cord which, from gel-filtration experiments on 'Bio-Gel', were found to be smaller than cytochrome *c*. Lumsden *et al.*[20] previously investigated diffusible polypeptides obtained by mild treatment of 'basic protein' with alkali. Their most highly purified product differed from the polypeptides described in this communication in that its R_F value was 0·5 rather than 0·00–0·01 in butanol–acetic acid–water. It is probable that the encephalitogenic 'far cathodic protein' isolated by Roboz-Einstein, Robertson, D Caprio and Moore[24] is equivalent to our fractions, which show the faster-moving cationic bands '*e*', '*f*', '*g*' and '*h*' of Fig. 1 but, from preliminary results on the ultracentrifuge, these last-mentioned authors concluded that their material had a molecular weight of 18,000–20,000. We now believe that this apparently much higher molecular weight must be due to peptide aggregation, as occurs with histones. Kibler[25] has observed that his encephalitogenic preparation, which was similar to that of Kies[2], is dissociated by raising the ionic strength.

Finally, although gel-filtration in phenol–acetic acid–water is useful in assessing the approximate molecular weight of the encephalitogenic factor(s), it is not so convenient for large-scale isolation of the peptides. Preliminary experiments on the polyacrylamide gel, 'Bio-Gel *P*-6', show that it can be used to prepare, from the acid potassium chloride extract, the fractions containing cationic bands equivalent to '*e*', '*f*', '*g*' and '*h*' in Fig. 1. 'Bio-Gel *P*-6' is claimed to have an exclusion limit of 4,600 mol. wt. Using this material, with formic acid–acetic acid–water (1 : 4 : 45 by volume) as solvent, bands '*f*' and '*g*' were eluted from a column with about the same elution volume as was required for the *B* chain of insulin (molecular weight 3,500).

In summary, a fraction composed of basic polypeptides of unusual amino-acid composition has been prepared by gel-filtration from extracts of defatted spinal cord. From the gel-filtration experiments using phenol–acetic acid–water as solvent it is suggested that the molecular weight of the peptide fraction, which can produce experimental allergic encephalomyelitis, is about 3,000.

Part of this work was carried out under the Eleanor Brooke fellowship for research in multiple sclerosis provided by the Hull Branch of the Multiple Sclerosis Society of Great Britain. We also thank Mr. M. Knowles for technical assistance, and Dr. T. A. A. Dopheide for a sample of *B* chain of insulin.

PHYSIOLOGY

Active Transport of Iron by Intestine: Effect of Erythropoiesis stimulated by Phenylhydrazine

Intestinal absorption of radio-iron in intact rats was increased during the enhanced erythropoiesis which followed haemolysis induced by phenylhydrazine[1]. Similarly, erythropoiesis stimulated by acetylphenylhydrazine in dogs also increased iron absorption *in vivo*[2]. This report describes experiments designed to study the effects of increased erythropoiesis in the rat on iron transport across everted duodenal gut sacs *in vitro*. The *in vitro* technique has defined an active transport mechanism for iron absorption[3,4] which varies adaptively with dietary iron and pregnancy[5] and, as will be shown, the cellular mechanism is also involved in the response to increased erythropoiesis.

Male, albino, Sherman strain rats, 80–140 g, were injected subcutaneously with 100 mg/kg body-weight of phenylhydrazine-HCl (recrystallized from boiling water) dissolved in 0·9 per cent sodium chloride, and controls received saline alone. Seven days later rats were killed, the proximal 10 cm of small intestine excised and two consecutive everted gut sacs prepared[4], each 5 cm long. Mean wet weights of the proximal and distal sacs were approximately 770 and 500 mg, respectively. Sacs were incubated in Warburg vessels under oxygen, at 37° C, for 2·5 h in the ambient medium previously described[4], containing 0·1 mM freshly prepared ferrous sulphate, 0·8 mM sodium ascorbate, and sufficient $^{59}FeSO_4$ (Abbott Laboratories, Oak Ridge) to give about 10,000 c.p.m./ml. in a well-type scintillation counter. After incubation sacs were drained, and iron-59 and iron in the mucosal and serosal media were estimated as previously described[4]. Heparinized capillary tubes were used for haematocrit determinations.

Following phenylhydrazine injection the initial mean haematocrit, 42 per cent, decreased to 29 per cent at 3 days and returned to the initial control value at 7 days. Everted gut sacs were then prepared from thirty-one control and forty phenylhydrazine-treated rats and tested *in vitro* (Table 1). Phenylhydrazine treatment increased net transfer of iron (estimated chemically) to the serosal surface by 19·7 per cent ($P < 0·05$) and 54·7 per cent ($P < 0·01$), respectively, in the proximal and adjacent distal segments. Final iron-59 concentration ratios serosal/mucosal were increased correspondingly by 24·4 per cent ($P < 0·02$) and 54·8 per cent ($P < 0·001$) in the proximal and distal segments, respectively. Gut sacs prepared from intestine more than 10 cm distal from the pylorus showed no clear effect of prior phenylhydrazine treatment.

Table 1. Effect of Prior Phenylhydrazine on Iron Transport by Everted Duodenal Gut Sacs *in vitro*

Group	No.	Net Fe transfer to serosal medium mμmoles/gut sac		Iron-59 concentration ratio serosal/mucosal	
		Proximal sac*	Distal sac	Proximal sac	Distal sac
Control	31	31·4 ± 10·5†	12·8 ± 6·6	4·5 ± 1·4	2·0 ± 1·1
Phenylhydrazine	40	37·6 ± 12·0	19·8 ± 10·3	5·6 ± 2·1	3·1 ± 1·4
P value		< 0·05	< 0·01	< 0·02	< 0·001

* Two gut sacs were prepared from the proximal 10 cm of rat small intestine and results are shown for the more proximal and adjacent distal sac.
† Mean ± *S.D.*

The results indicate that the mucosal mechanism for active transport of iron is responsible, in part at least, for enhanced absorption observed after phenylhydrazine treatment. Treated rats were not anaemic at the time of the experiment, and the stimulus for increased iron transport was apparently increased erythropoiesis following haemolysis[1]. Response of the iron transfer mechanism observed *in vitro* was limited to the proximal 10 cm of small intestine and distinctly less in magnitude than the more than two-fold increase observed in intact rats[1]. Thus factors other than the mucosal mechanism studied here may participate in the response to increased erythropoiesis *in vivo*. Increased iron transport observed in the present experiments also differs from that following a low iron diet[5]. Dietary restriction yielded much greater increases in transport *in vitro*, and the most proximal segment showed the greatest effect.

Increased Active Transport of Glucose through the Intestine during Pregnancy

A well-known aspect of the physiological adaptation to pregnancy is the increase in ingestion of food as a result of stimulation of the lateral nuclei of the hypothalamus.

From a teleological point of view, it might be thought that an increase in the absorptive capacity of the intestine would be associated with this increase in ingestion. It is, in fact, known that iron is absorbed more rapidly during pregnancy, in proportion to the development of the haematopoietic organs of the foetus[1], but few other investigations of intestinal absorption in pregnancy have been carried out.

We have therefore investigated the effect of pregnancy on the absorption of *d*-glucose—one of the most actively transported substances. Other experiments dealing with the absorption of glycine are in progress. The Sols y Ponz technique of successive absorptions *in vivo* was used, as in previous investigations[2].

Table 1. Influence of Pregnancy on the Absorption Rate of *d*-Glucose through the Intestine of Rats *in vivo*

No. of rats	Glucose (mmole)	Intestinal* absorption (μmole/cm)
Not pregnant		
8	300	43·3 ± 0·8
9	150	20·0 ± 0·05
12	75	13·0 ± 0·02
7	20	5·0 ± 0·09
Pregnant		
9	300	52·1 ± 0·5
10	150	26·1 ± 0·7
10	75	16·8 ± 0·2
7	20	7·0 ± 0·4

* Time of absorption, 30 min

Thirty-six white Wistar rats, weighing from 180 to 200 g and 12–15 days pregnant, and a control group of thirty-six rats of similar characteristics but not pregnant, were perfused with solutions of 300, 150, 75 and 20 mM glucose at a pressure of 12 cm of water for 30 min. In each animal, four successive absorptions were carried out.

In Table 1 the average values for both types of experiments are indicated with their corresponding standard errors. The results show a very significant increase ($P < 0·01$) in the absorption of glucose in the pregnant rats over that in the controls. This increase is observed with all the concentrations of glucose, amounting to 21 per cent for 300 mM, and 40 per cent for 20 mM.

Similar results have been found for glycine[3]. The observed increase in the absorption rate is another example

of the modification of the active transport of glucose through the intestine in different functional states, such as diabetes[4], fasting[5] and hyperthyroidism[6], and these results suggest that in studying the maintenance of homoeostasis of certain body constituents it is necessary to take into account this activity of the intestinal mucosa, in addition to increased ingestion and other variations in the activity of the digestive system.

PHARMACOLOGY

Antagonism of Colistin-sulphonamide Synergism by *para*-Aminobenzoic Acid

Russell[1] reported an *in vitro* synergism between colistin methane sulphonate and sulphonamide drugs using a number of *Proteus* isolates. He found that the combinations were bactericidal at therapeutic levels, that the ratios of the drugs were not critical, and that the effect was present over a wide range of hydrogen ion concentration. The observations were extended to polymyxin *B* sulphate and sulphonamides with similar results.

Since colistin alters the permeability of certain bacteria[2], the possibility was considered that the synergism may be mediated by an alteration of the cytoplasmic membrane to a degree insufficient to cause bacteriostasis in itself, but sufficient to permit the passage of sulphonamides into the cell. If such were the case, the actual inhibition of growth would be a result of a block in folic acid formation and would be overcome by *p*-aminobenzoic acid[3].

To test this, *Proteus vulgaris* and *P. mirabilis* were inoculated into culture tubes containing 'Bactotryptic' soy broth (Difco), with and without *p*-aminobenzoic acid (PABA), and with colistimethate sodium and certain sulphonamide drugs, singly and in combination. Growth was assessed by means of the optical density of each culture after incubation for eleven hours at 37° C. Results were expressed as the percentage of inhibition as compared with appropriate control cultures without drugs.

Table 1 shows the results of one experiment in which sulphanilamide was used; Table 2 shows a similar pattern when the sulphonamides used were extracted with water from sensitivity disks (Baltimore Biological Laboratories) each of which contained 1·0 mg total of a mixture of sulphadiazine, sulphamethazine, and sulphamerazine (triple sulpha). The *Proteus* isolates had a low order of sensitivity to sulphonamides alone and to colistimethate sodium alone. The combination of the two drugs resulted in much greater inhibition, and this enhanced activity was largely overcome by PABA. Attempts to antagonize the synergism with folic acid were not successful; the extent to which this may be related to the inability of the organisms to incorporate or utilize pre-formed folic acid has not been determined.

Table 1. Synergism between Colistimethate Sodium and Sulphanilamide and its Reversal by PABA

	P. vulgaris Inhibition (per cent)		*P. mirabilis* Inhibition (per cent)	
	No PABA	With PABA	No PABA	With PABA
Sulphanilamide	7	0	25	2
Colistimethate sodium	10	2	8	15
Combined	71	7	86	15

Sulphanilamide, 400 μg/ml.; colistimethate sodium, 50 μg/ml.; PABA, 0·01 per cent.

Table 2. Synergism between Colistimethate Sodium and Triple Sulpha and its Reversal by PABA

	P. vulgaris Inhibition (per cent)		*P. mirabilis* Inhibition (per cent)	
	No PABA	With PABA	No PABA	With PABA
Triple sulpha	13	0	5	0
Colistimethate sodium	14	7	10	3
Combined	61	10	72	4

Concentrations same as in Table 1.

The present results tentatively suggest that the sulphonamide-colistin synergism is mediated through an initial alteration by colistin of the permeability of the cytoplasmic membrane of *Proteus* species in such a way as to permit entry of the sulphonamide into the cell. The sulphonamide then retards cell replication by interference with folic acid synthesis.

This work was aided by a grant from the National Institutes of Health, U.S. Public Health Service. 'Coly-Mycin' diagnostic (colistimethate sodium) was provided by the Warner-Lambert Research Institute, Morris Plains, New Jersey—the research affiliate of Warner-Chilcott Laboratories.

HISTOLOGY

Branched Cells in the Epidermis of the Sheep

Branched cells positive for alkaline phosphatase, and which are darkened by osmium iodide, have been found in the epidermis of certain African primates[1–3]. Other dendritic cells have been revealed by gold impregnation and methylene blue in the non-pigmented epidermis of guinea-pigs, rabbits and man[4], and by gold impregnation and electron microscopy in the epidermis of man[5].

Histochemical preparations for acetylcholinesterase have revealed numerous large branched cells in the epidermis and upper external sheaths of the follicles of several breeds of sheep (Merino, Southdown, Suffolk, English Leicester and Border Leicester). By contrast, such acetylcholinesterase-positive branched cells were not revealed in other species investigated at the same time (bandicoot *Perameles nasuta*, possum *Trichosurus vulpecula*, laboratory rabbit, laboratory rat, and ox). Neither the techniques for butyrylcholinesterase nor for alkaline phosphatase revealed these branched cells in sheep skin. Moreover, they did not stain with osmium iodide or gold chloride and did not produce a positive 3,4-dihydroxyphenylalanine (DOPA) reaction.

The regions of the sheep examined included several producing hair and several producing wool. Samples were also taken from four regions (lower lip, between nares, nipple and vulva) devoid of follicles. In addition, samples were taken from the placenta of a full-term sheep foetus with plaques of wool follicles on the amnion[6]. Acetylcholinesterase-positive branched cells were found on all of the regions where there were follicles, but they were not found in the non-follicular regions. Even on the amnion the branched cells were confined to the plaques having follicles.

The processes of the branched cells (Fig. 1) extend throughout the epidermis, some even to the cornified layer, but the perikarya are evenly spaced (about 50μ

apart) and are located in the basal layer near the dermo-epidermal junction. Although the population densities of melanotic melanocytes in the epidermis and follicles vary greatly between sheep, the number of branched cells per unit area was essentially the same in all sheep.

The population density of these branched cells was not modified by contact with solid carbon dioxide for up to 30 sec duration in any of the sheep examined, nor by exposure to ultra-violet light, except in a Merino with a very sparse population of melanotic melanocytes. In this animal there was a reduction of the acetylcholinesterase-positive cells after a moderate exposure to ultra-violet radiation and an almost complete loss of the cells from the epidermis, but not from the upper external sheaths of the follicles, following a more severe ultra-violet burn. In the other animals so treated, a dark-skinned Merino and a Southdown, both with numerous melanotic melanocytes, there was tanning but not burning, and the number of positive branched cells per unit area was not changed. From these limited observations it appears that the basal layer, including the perikarya of branched cells, is protected from ultra-violet radiation by the presence of melanin in the melanocytes.

The precise nature and function of these cells are not known. Even though these branched cells in the sheep are acetylcholinesterase-positive and do not react for alkaline phosphatase or with osmium iodide, they seem to be generally similar in morphology and pattern of distribution to the branched cells of some African primates[1-3]. They also appear similar in morphology to the epidermal dendritic cells which have been revealed in other animals[4,5]. The similar distribution of branched cells in epidermal regions with melanocytes and in epidermal regions without melanocytes indicates that branched cells in sheep are not effete melanocytes. It is conceivable that these branched cells are derived from stem cells which can mature and differentiate either into the Langerhans type[5,7] or in the direction of a melanotic melanocyte.

Fig. 1. Acetylcholinesterase-positive branched cells in the basal layer of the epidermis of the mid-lateral region of the trunk of an adult Merino ewe. Frozen section (40μ thick) cut parallel to the skin surface

Alternatively, it may be that at the dermo-epidermal junction there are stem cells for melanocytes and separate stem cells for branched cells, both derived from the neural crest. Branched cells may well have a supportive role, or perhaps a trophic function as indicated by their regular pattern (Fig. 1) and close proximity to all epidermal cells below the stratum corneum.

We thank Mr. D. E. Hollis for his skilled histochemical preparations.

HISTOCHEMISTRY

Particles in Leucocytes of Normal Humans Beings after Negative Staining in Electron Microscopy

The negative staining technique for the study of cells and cellular components by electron microscopy has been described by Almeida and Howatson[1]. A similar method has been applied to study the morphology of the Moloney leukaemia virus in megakaryocytes in experimentally infected mice[2]. Recently, virus-like particles have been described in the plasma of many leukaemic humans examined by a negative-staining technique[3-6]. This report describes the application of a similar technique to leucocytes of normal human beings.

Leucocytes of normal adult humans were separated from heparinized fresh blood (0·5 mg heparin to 1 cm³ of blood) from five healthy individuals. The erythrocytes were allowed to settle at room temperature for 1 h. The plasma, rich in leucocytes, was drawn off, centrifuged 15 min at 10,000*g*, washed with 0·05 M citrate buffer *p*H 6·8, recentrifuged, and resuspended in the citrate buffer. (Some agglutination occurred.) The cells were frozen at −65° C, thawed, and mixed with 2 per cent phosphotungstic acid (PTA) (*p*H 7·0) to a final concentration of 1 per cent PTA. They were examined with an EMU-3 microscope.

Particles were seen within leucocytes and emerging from them (Figs. 1 and 2). The specific types of leucocytes could not be identified because of distortion during the procedure. The particles varied in shape and included toroidal, tailed, reticulated and stranded forms. The toroidal particles were relatively numerous and ranged in diameter from 90 to 350 mμ. Their nature is not definitely known, but we suspect that they consist of nuclear material because of their central location when seen in intact cells.

Because many of the smaller particles from normal individuals bear a striking resemblance to particles described by Dalton[2] in leukaemic mice, it appears that the negative-staining technique must be used with caution in identifying viruses within cells or in preparations made from cells. This is in agreement with Almeida's conclusion that preparations of the blood of normal people reveal many particles in the same size range as virus particles. These may be mistaken for virus particles unless other criteria are considered regarding the morphology of the

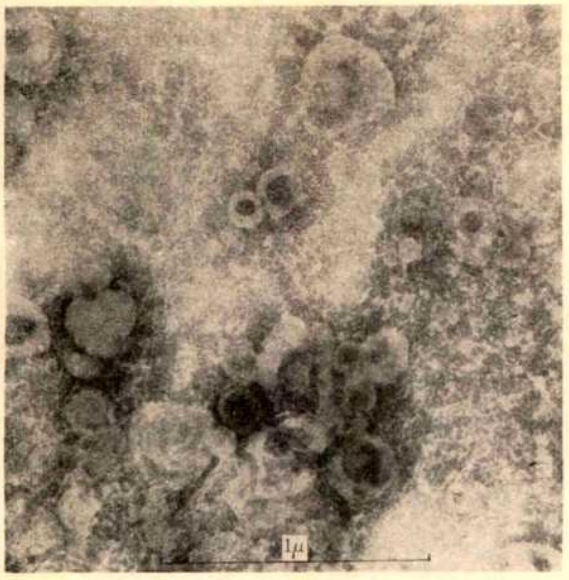

Fig. 1

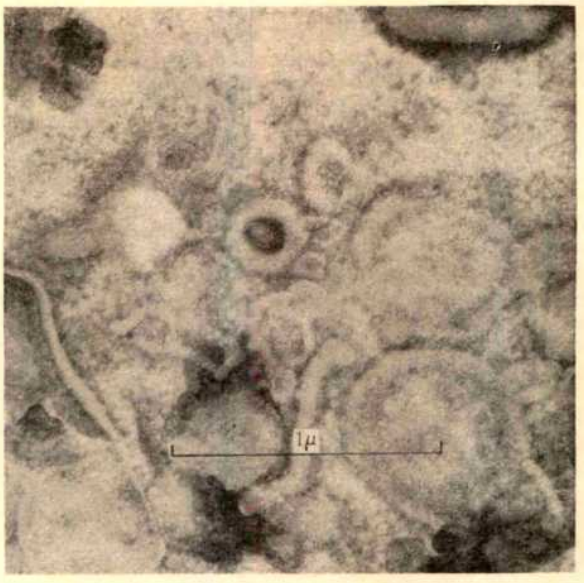

Fig. 2

Figs. 1 and 2. Particles emerging from a leucocyte of a normal human being after heparinized cells were frozen, thawed and mixed with PTA. Toroidal forms are common. Other particles in evidence include reticulated, stranded, encapsulated and tailed forms

particles known to be associated with negatively stained materials.

We therefore consider that morphological criteria by the PTA technique are inadequate when searching for new human leukaemogenic viruses in tissue, since normal human cell components have a strikingly similar morphology to well-known murine leukaemia viruses by the PTA technique.

IMMUNOLOGY

Failure to transfer Sensitivity to Skin Homografts by Means of 'Immune' Lymphoid Cells in Diffusion Chambers

ALTHOUGH there has been a considerable number of reports dealing with the susceptibility of dissociated cellular homografts of many tissues, notably those derived from the lymphohaematopoietic system, to humoral isoantibodies[1], the majority of attempts to demonstrate that humoral factors play any significant part in the destruction of skin and other solid tissue homografts have failed[2]. Indeed, most of the available evidence sustains the premise that a 'cellular' immunity is involved and that the demise of a homograft is causally related to its characteristic infiltration by mononuclear cells.

What might be construed as a serious challenge to this thesis are the reports of Najarian and Feldman of the transferability of sensitivity to skin homografts in mice and guinea-pigs by means of viable suspensions of 'immune' lymphoid cells, enclosed within cell-impenetrable 'Millipore' diffusion chambers, implanted either intraperitoneally or subcutaneously into isologous hosts[3,4]. Similar findings have been reported in rabbits[5]. Our preliminary, small-scale attempts to confirm these observations, using both immunologically tolerant and normal mice as hosts, were unsuccessful[6]. However, we felt that the far-reaching implications of Najarian and Feldman's observations[3,4] concerning the mechanism of homograft destruction justified a more extensive investigation, and this communication reports our findings.

As before[6], every attempt was made to follow Najarian and Feldman's protocols as closely as possible. Adult mice of both sexes, derived from domestically maintained sub-lines of strains *A* and *CBA*, were used throughout, and both the possible donor/recipient combinations were tested. The median survival times (± standard error) of skin homografts exchanged between members of these strains, as determined from a histological appraisal of biopsied specimens removed at regularly spaced intervals, are[7]:

$CBA \rightarrow A$	$10{\cdot}2 \pm 0{\cdot}3$ days
$A \rightarrow CBA$	$11{\cdot}0 \pm 0{\cdot}3$ days

Sensitization of donors of immune lymphoid cells was achieved by grafting them bilaterally with skin homografts followed, 2 days later, by an intraperitoneal inoculation of a suspension of 10 million homologous spleen cells in Hanks's balanced salt solution. Nine days after exposure to the skin homografts these animals were killed and their spleens, axillary, brachial, cervical and mesenteric nodes excised, pooled and dissociated in Hanks's solution containing polyvinylpyrrolidone (final concentration 0·35 per cent v/v) to produce a cell suspension. On the basis of trypan blue dye exclusion tests, not less than 90 per cent of the cells were viable.

0·12-ml. portions of this suspension, containing about 200 million cells, were introduced into a series of sterile 'Millipore' chambers (pore size 100 mμ) which were then sealed. Two of these were then inserted into the peritoneal cavity of each of the isogenic host mice.

In some experiments host mice were challenged with skin homografts from the alien donor strain immediately after receipt of the diffusion chambers; in others, test grafting was delayed for 2 days. Care was taken to avoid areas of 'active' skin as donor sites for the test grafts. Instead of suturing the grafts in place, as did Najarian and Feldman, we used our standard procedure of keeping the grafts in position on their beds—afforded by the intact panniculus carnosus with its overlying vasculature—under light pressure by means of dressings around the thorax[8].

In some experiments, the survival times of the test grafts were assessed visually, scoring daily the degree of epithelial survival from the sixth day onwards. In others, the grafts were removed on the sixth post-operative day for histological appraisal of the percentage of epithelial survival.

Diffusion chambers containing normal instead of immune lymphoid cell suspensions were implanted into some groups of mice, and these acted as our controls. Our criterion of transfer of immunity was any evidence of accelerated destruction of test grafts borne by recipients of immune cells.

Table 1. Comparison of the Fate of Test Skin Homografts on Mice bearing Diffusion Chambers containing Isologous Lymphoid Cells from (*a*) Normal and (*b*) Specifically Sensitized Mice

Strain combination	Immunological status of transferred cells	No. of hosts tested	Appraisal of test skin homografts: Survival times (days)	Or percentage of epithelial survival in 6-day biopsy specimens
CBA→*A*	Normal	12	9, 4×10, 4×11, 2×12, 13 (MST = 10·2 ± 1·12)	—
	Sensitized	20	9, 2×10, 7×11, 5×12, 13, 14, 3×15 (MST = 11·5 ± 1·16)	—
	Normal	19	—	13×100, 3×95, 75, 2×50
	Sensitized	20	—	6×100, 7×95, 5×75, 2×50
A→*CBA*	Sensitized	9	9, 7×10, 12 (MST = 10·2 ± 1·06)	—
	Normal	13	—	11×100, 95, 75
	Sensitized	17	—	12×100, 2×95, 75, 2×25

Table 1 summarizes the various tests carried out and their findings. Since the results of delaying test grafting for 2 days were similar to those obtained when test grafts were applied at the time of insertion of the diffusion chambers, the data have been pooled. With neither donor/recipient strain combination was there any evidence that sensitivity had been transferred. The median survival times of *CBA* grafts on *A* strain recipients bearing chambers containing normal or immune lymphoid cells were 10·2 ± 1·12 and 11·5 ± 1·16 days, respectively. The *CBA* recipients of sequestered immune node cells rejected their *A* skin test grafts within about 10 days (median survival time 10·2 ± 1·06 days).

Histological scores of the degree of epithelial survival in the 6-day biopsy specimens were in complete accord with the determinations of survival time. At the sixth post-operative day, 90 per cent of the grafts exhibited high degrees of survival of a hyperplastic epidermis characteristic of first-set skin homografts. With the *CBA* → *A* combination, several test grafts on the recipients of sensitized node cells survived a few days longer than on the controls. A likely explanation of this slight prolongation is that it is due to the immunological enhancing activity of antibody released by the sequestered immune node cells[9].

In view of the close similarity of design between the present experiments and those of Najarian and Feldman, it is difficult to account for the discrepancy in the results obtained. The essential differences between the two procedures were: (*a*) bilateral grafting of the donors of the immune lymphoid cells rather than giving them a single mid-dorsal graft, and (*b*) securing the test grafts in place by means of dressings, rather than suturing.

That the lymphoid cell suspensions introduced into our chambers were viable was attested by the results of the dye exclusion tests, and also by the fact that a small number of cells prepared by this procedure and injected intraperitoneally into tolerant mice were highly effective in procuring the destruction of hitherto long-tolerated grafts[6].

This work was supported in part by a grant from the National Institutes of Health, U.S. Public Health Service, and fellowships from the Helen Hay Whitney Foundation and the U.S. Public Health Service. We thank Dr. Joseph Feldman for helpful suggestions and for providing us with polyvinylpyrrolidone, and Mrs. S. Schroeder and Mr. G. Sawchuck for their technical assistance.

Inhibitory Effect of Carcinostatic Agents on Antitumour Activity of Immune Lymphoid Cells

It has been widely demonstrated that *in vivo* application of carcinostatic agents inhibits the host immune response, namely, inhibition of antibody production by antimetabolites[1–4], alkylating agents[1,5] and antibiotics[6,7], and prolongation of homograft survival by a nitrogen mustard derivative[8]. Investigations of the mode of action of these agents on the immune function of lymphoid cells sensitized with homologous cells would provide interesting information on the mechanism of action of the lymphoid cells in transplantation immunity, since some of these agents have been known to act on the specific sites of the cellular functions.

We have recently demonstrated that the peritoneal fluid cells of Donryu rats[9] immune to homologous tumour, Yoshida sarcoma, showed a marked antitumour action both in transfer system and in diffusion chamber[10]. The experiment described here shows the effects of several carcinostatic agents on the cellular immunity of the peritoneal fluid cells sensitized with Yoshida sarcoma and on the growth of the tumour cells.

Peritoneal fluid cells were collected, following intraperitoneal injection of 5 ml. heparin–Hanks's solution in a rat, from male Donryu rats which had been repeatedly immunized with Yoshida sarcoma by a method previously reported[10]. The pooled fluids, containing 10^7 cells/ml., were incubated for 30 min at 37° C both with and without the carcinostatic agent. The cells were sedimented and washed twice with fresh Hanks's solution. The washed cells were then suspended in Hanks's solution with a concentration of 10^7 peritoneal fluid cells/ml. In all experiments in which the viability of these cells was examined by the eosin stain test, more than 90 per cent of them were demonstrated to be viable at this time. The suspension was mixed with an equal volume of suspension containing 10^5 Yoshida sarcoma cells/ml., and the mixture was kept at 25° C for 10 min. Two ml. of the mixture was intraperitoneally injected into a recipient Donryu rat, and the tumour development was observed. When the antitumour function of the immune peritoneal cells diminished, the recipient animals died due to tumour growth.

Table 1. Effects of Carcinostatic Agents on the Anti-Yoshida Sarcoma Function of Immune Peritoneal Fluid Cells and on Yoshida Sarcoma Cells

Series 1

Agent	Cells for inoculation	Concentration of agent for treatment of cells						
		No. of recipient rats dying with tumour/animals tested						
Nitrogen mustard		0	0·0016	0·016	0·16	1·6	16 μg/ml.	Control
	YS + treated PFC	0/10		0/10	3/10	10/10	10/10	10/10
	Treated YS	3/3	6/6	2/6	0/6			
Mitomycin *C*		0	0·2	2	20	100	μg/ml.	
	YS + treated PFC	1/9	0/5	0/9	3/9	4/4		10/10
	Treated YS		3/3	1/3				
Actinomycin *D*		0	0·06	0·6	6	μg/ml.		
	YS + treated PFC	0/5	1/5	0/5	4/5			5/5
	Treated YS		3/3	2/3	0/3			
Puromycin		0	0·48	4·8	48	μg/ml.		
	YS + treated PFC	0/5	1/5	1/5	1/5			5/5
	Treated YS		3/3	3/3	3/3			
6-Mercaptopurine		0	150	1,500		μg/ml.		
	YS + treated PFC	0/5	1/5	1/5				5/5
	Treated YS		3/3	3/3				

Series 2

Actinomycin *D*		0	0·3	0 65	1 3	2 6 μg/ml.	Control	
	YS + treated PFC	0/5	0/5	0/5	5/5	4/5	5/5	
	Treated YS	3/3	3/3	3/3	1/3	0/3		
Mitomycin *C*		0	4	8	16 5	33	66 μg/ml.	Control
	YS + treated PFC	0/5	0/5	0/5	2/5	3/5	5/5	5/5
		0·2	0·4	0·8	1·65	3 3	6·6 μg/ml.	
	Treated YS	3/3	3/3	3/3	2/3	1/3	0/3	

Underlining indicates that the first group was significantly affected by an agent, and the concentration of the agent was designated as the minimum effective concentration to the treated cells. Each animal in the first and second groups was given 10^7 cells of treated PFC (peritoneal fluid cells from the immune rats) mixed with 10^5 YS (Yoshida sarcoma cells), and 10^7 cells of treated YS, respectively. Control animals were transplanted with 10^5 YS cells alone intraperitoneally.

The anti-Yoshida sarcoma activity of an agent was tested in the similar way to that already described. Suspensions containing 10^7 tumour cells/ml. were incubated with the agent in Hanks's solution and the twice-washed 10^7 cells were injected intraperitoneally into a rat.

It can be seen from Table 1 that in Series 1 exposure to nitrogen mustard, mitomycin *C*, or actinomycin *D* at certain concentrations abolished both the antitumour function of the sensitized peritoneal fluid cells and the growth of Yoshida sarcoma cells; on the other hand, puromycin and 6-mercaptopurine did not act on these cells even at higher concentrations.

The antibiotics mitomycin *C* and actinomycin *D* are especially interesting, since it is known that they interact specifically with nucleic acids. Bloom *et al.*[11] reported that exposure to mitomycin *C* *in vitro* at rather high concentration abolished the capacity of cellular transfer of delayed-type hypersensitivity in sensitized lymphoid cells. Actinomycin *D* has been found to be an effective inhibitor of antibody formation in lymphoid cells[12–14], and this antibiotic acted differentially on the immunologically determined and competent cells[13]. The heterologous host–antigen systems were used in these *in vitro* experiments.

Thus a more detailed study of the action of actinomycin *D* and mitomycin *C* on the immune peritoneal fluid cells and on Yoshida sarcoma cells was undertaken. The results of Series 2 in Table 1 show that the minimum effective concentrations of actinomycin *D* to the sensitized peritoneal fluid cells and to Yoshida sarcoma cells were 1·3 μg and 1·3 μg/ml., respectively, while those of mitomycin *C* were 16·5–33 μg and 3·3 μg/ml. Thus, the ratios of minimum effective concentration to the immune peritoneal cells against that to tumour cells were 1 for actinomycin *D* and 5–10 for mitomycin *C*. In the case of nitrogen mustard, the ratio was approximately 10 (Table 1—Series 1). If these agents act in a similar manner on the sites of the cells which control growth and viability of the tumour cells (or antihomograft function of the lymphoid cells) the ratios may be equal among them. It is possible that the significant difference of the ratio indicates that the antitumour function of the sensitized peritoneal fluid cells is specially inhibited by short-term exposure to actinomycin *D*.

It has been known for some time that actinomycin *D* inhibits DNA-directed RNA synthesis[15,16], and, moreover, that when the RNA synthesis is inhibited the immune cells lose their immunological function[11]. It is thus possible that the antitumour function of the sensitized peritoneal fluid cells in the present experiment are related to an RNA-dependent function of the cells. However, whether the duration of the viability of the cells before and after exposure to the carcinostatic agents is equal, and whether the non-specific affinity to the cells is different among these agents, require further investigation.

PATHOLOGY

Increased Localization and Incorporation of Iododeoxyuridine into Tumour DNA *in vivo* when coupled to Polycation

There is some evidence that tumour cell surfaces are in a hyperanionic state which could be associated with lowered intercellular adhesion and contact inhibition of mitosis[1,2]. If cells of tumour tissues have a higher anionic surface charge or the hyperanionic state lasts for a greater portion of the intermitotic cycle than other growing cells of the body, it should be possible to accumulate cations in favour of the tumour cell surface. By coupling cytotoxic drugs to these cations it might be further possible to attain lethal toxicity in tumour cells before destroying other vital tissues.

This communication describes the incorporation of the cytotoxic and radiosensitizing drug 5-iododeoxyuridine (IUdR) into the DNA of various tissues of the C_3H strain of mice bearing spontaneous mammary tumours after prolonged injection of either the free drug or its water-soluble complex with polycation. The polycation polyethylene imine (PE) (molecular weight $3–5 \times 10^3$) was complexed with IUdR or its derivative 5-iododeoxycytidine monophosphate (IdCMP) which provides a stronger salt link by way of its phosphate group to the basic nitrogen atom of PE. IdCMP, which is readily deaminated by mammalian tissues to yield iododeoxyuridine monophosphate, was prepared by direct iodination of IdCMP (ref. 3). Complex formation was achieved by simple mixing in aqueous solution and integrity of the product was confirmed by elution from 'Sephadex *G*-25' as a single component.

The first aim of these experiments was to trace the relative incorporation of IUdR into tumour DNA and DNA of other tissues known to incorporate more IUdR than tumour, namely, spleen and intestinal mucosa[4]. Leucopenia results from IUdR administration at doses subtoxic to tumour tissue even though bone marrow DNA contains less IUdR than tumour DNA, so white blood cell counts were included in these experiments.

The second aim was to discover conditions which would produce sufficient IUdR replacement of tumour DNA thymidine to render it lethally radiosensitive. It has been shown that 7–9 per cent replacement of DNA thymidine by IUdR in human cells *in vitro* produces a radiosensitization factor of 1·6 (ref. 5), but toxic doses of IUdR given systemically *in vivo* result in only 1–2 per cent replacement of tumour DNA thymidine[6]. If 5-fluorodeoxyuridine (FUdR) is given simultaneously to inhibit thymidine synthesis, IUdR incorporation in DNA of dividing cells can be increased at the expense of greater toxicity—chiefly leucopenia. In these experiments FUdR or its derivative 5-fluorodeoxycytidine monophosphate (FdCMP) was coupled along with IUdR or IdCMP to PE such that the iodine : fluorine ratios were 2·5 : 1 or 10 : 1. The tumour-localizing compound[7], 1 : 4-naphthaquinol-*bis*disodium phosphate ('Synkayvite', Roche), was also coupled to the drug-polycation complex in the expectation that it might favour accumulation on the tumour cell surface even further. Drugs and their complexes were injected subcutaneously for 5 days, after which blood was sampled from a tail vein for the white cell count. The animals were then killed and the intestines removed into ice-cold 0·14 M sodium chloride; 0·02 M to versene at *p*H 8·0. Spleen and tumour tissue free of necrotic debris were next removed and placed on dry ice. Intestinal contents were lightly squeezed out, the lumen opened and epithelium rapidly scraped off into 0·02 M sodium chloride containing 0·02 M versene at *p*H 8·0 and 1 per cent sodium lauryl sulphate. Tumour and spleen were thawed out and homogenized in the same medium. DNA was then prepared from these homogenates in a fibrous deproteinized form by the method of Kay *et al.*[8], which excludes all sources of iodine other than incorporated IUdR. After accurate assay by the diphenylamine reaction, 100–200 μg samples of DNA were then ashed with sodium bicarbonate and iodide content measured by the arsenious acid/ceric sulphate titration method described by Szabo[9]. Although accurately reproducible, this method results in 20–25 per cent losses of iodine during ashing.

Table 1, line (*a*), confirms the leucopenic effect and greater incorporation of IUdR into spleen and mucosae DNA than tumour DNA when free nucleosides are used. Presence of PE restores the white cell count to normal ($3·5–4·5 \times 10^3$/mm^3 in these animals); increases overall IUdR incorporation and improves localization in favour of the tumour (line *b*). The incorporation and tumour localization of IUdR are even greater when PE-coupled nucleotides are used (line *d*).

Table 1. Incorporation of IUdR into DNA of Tumour, Spleen and Intestinal Mucosa after Administration of IUdR and FUdR in the Ratio 2·5 . 1

	μg iodine/mg DNA (1) Tumour	(2) Spleen	(3) Mucosa	Ratio I/II*	Ratio I/III*	White cell count/ mm^3 × 10^3
(*a*) Free nucleosides	0·67	0 82	1·92	0 82	0·35	1·6
(*b*) (*a*) with PE	1 98	1·52	3·55	1·30	0·55	5·9
(*c*) Free nucleotides	1·81	2·01	2·82	0·90	0 64	0 6
(*d*) (*c*) with PE	2·44	1·90	3·94	1·28	0·62	3·4

All results are the mean of three animals. Daily dosage divided into three 8-hourly injections subcutaneously, in 0·2 ml. water for 5 days. (*a*) IUdR 50 mg, FUdR 20 mg/kg/day; (*b*) as (*a*) coupled to 10 mg PE/kg/day; (*c*) IdCMP 60 mg, FdCMP 24 mg/kg/day; (*d*) as (*c*) coupled to 10 mg PE/kg/day.
* Ratios are calculated from the individual iodine assay data, then averaged.

In Table 2, data from several types of experiments differing slightly in their dosage schedule or drug vehicle have been pooled to evaluate the localizing effect of polycation and 'Synkayvite' on tumour DNA incorporation of IUdR. Animals, the results of which are shown in lines (*b*) and (*c*), have been paired under each of the slightly varying conditions. When 'Synkayvite' is coupled to the polycation-drug complex there is an increase of 28 per cent in the tumour : spleen ratio and 42 per cent in the tumour : mucosa ratio. The magnitude of standard deviation, however, renders these differences statistically insignificant. Further experiments under standardized conditions will be undertaken to confirm this effect when more FdCMP is available.

Table 2. Effect of Coupling 'Synkayvite' to Polycation Complex with IdCMP and FdCMP (Ratio 2·5 : 1) on the Localization of IdUR in Tumour DNA

	Tumour DNA iodine / Spleen DNA iodine	Tumour DNA iodine / Mucosa DNA iodine	White cell count/ mm^3 × 10^3
(*a*) Nucleosides only	0·86 ± 0·23 (12)	0 45 ± 0·19 (12)	1·01 ± 0·48 (12)
(*b*) Nucleotides with polycation	1·85 ± 1·26 (12)	0 69 ± 0 24 (12)	3·55 ± 0·81 (12)
(*c*) as (*b*) with 'Synkayvite'*	2·33 ± 1·46 (12)	0·98 ± 0·41 (12)	3 55 ± 1·02 (12)

(*a*) IUdR 50 mg, FUdR 20 mg/kg/day; (*b*) IdCMP 60 mg, FdCMP 24 mg coupled to 10 mg PE or 80 mg protamine free base/kg/day, (*c*) as for (*b*) coupled to 4 mg 'Synkayvite'/kg/day. Daily dose divided into either 3 × 8-hourly injections in 0 2 ml. water or 2 × 12-hourly injections in peanut oil emulsion (0·3 ml.) given subcutaneously for 5 days.
* In 3 animals 0 75 mg methotrexate/kg/day substituted for FdCMP.

Table 3 shows the results of using a 10 : 1 IUdR : FUdR ratio with and without PE and 'Synkayvite'. As judged by comparison of the white cell counts in line (*a*) of Tables 1 and 2, this increased ratio of IUdR to FUdR has a lower antimitotic effect, but incorporation of IUdR into tumour DNA is increased. The dosage schedule for line (*c*) Table 3 gives both the best localization and highest incorporation of IUdR into tumour DNA. The value of 3·2 μg iodine/mg DNA is equivalent to nearly 6·5 per cent thymidine replacement after compensating for iodine losses in the ashing step of the assay. By using PE-coupled nucleotides one can increase IUdR incorporation into tumour DNA over three-fold compared with free nucleosides. This could be due either to the protective effect of phosphate or polycation groups against enzymes which rapidly dehalogenate free IUdR, or to the pinocytotic transport of the intact complex into tumour cells such

Table 3. INCORPORATION OF IUdR INTO DNA OF TUMOUR, SPLEEN AND INTESTINAL MUCOSAE AFTER ADMINISTRATION OF IUdR AND FUdR IN THE RATIO 10 . 1

	'Synkayvite'	γ g Iodine/mg DNA			Ratio I/II	Ratio I/III	White cell count/ mm³ × 10³	No. animals
		I Tumour	II Spleen	III Mucosa				
(*a*) Nucleosides only	−	0 98	1·67	1·80	0·61	0·55	2·5	(2)
	+	1 21	1·32	1·28	0·92	0·94	2·4	(3)
(*b*) as (*a*) with PE	−	1·54	1·81	2 29	0·87	0·67	4·4	(3)
	+	2 25	1 86	3·00	1·50	0·75	4·5	(2)
(*c*) Nucleotides with PE	−	3 20	2·03	2 50	1·73	1·51	4·5	(3)
	+	2·80	1 96	2 18	1·30	1·58	3·8	(3)

(*a*) 70 mg IUdR, 7 mg FUdR/kg/day; (*b*) as (*a*) coupled to 10 mg PE/kg/day; (*c*) 80 mg IdCMP, 8 mg FdCMP, coupled to 10 mg PE/kg/ day. 'Synkayvite' where present at 4 mg/kg/day. Daily dose divided into 2 × 12-hourly subcutaneous injections in 0·3 ml. water for 5 days.

that IdCMP can enter directly into the DNA synthetic pathway. If this is true, then PE-coupled iododeoxycytidine triphosphate would be utilized even more efficiently since nucleoside triphosphates are the immediate substrates for DNA polymerase. This and other factors designed to increase the localization and incorporation of IUdR into tumour DNA *in vivo* still further are being investigated.

We thank Dr. R. Duschinsky, Hoffman–LaRoche, Inc., Nutley, N.J., for a gift of FdCMP. Part of this work was completed at the laboratories of the Imperial Cancer Research Fund, London, W.C.2.

RADIOBIOLOGY

On the Shape of the Dose-response Curve for HeLa Cells cultured *in vitro* and exposed to Gamma-radiation

PROGRESS in theoretical radiobiology depends very largely on the interpretation of dose-response curves; nowadays, interest is being focused on the reproductive survival of mammalian cells. Unfortunately research workers measure, not survival 'curves', but a limited number of discrete points. These data, even if free from artefacts which would render them meaningless, have such limited statistical significance that it is often possible to fit more than one mutually exclusive theoretical curve through them.

Much effort has been devoted to the development of the multi-target and multi-hit models of radiation damage at the cellular level[1–4]. If survival curves are plotted in the conventional way, that is, the fraction surviving on a logarithmic scale, versus dose on a linear scale, the multi-target model leads one to expect a dose-response curve which, after an initial shoulder, becomes straight; the multi-hit model would predict a curve which bends continuously and never straightens, although this curvature may be very small over the range of survival used in experimental investigations[3]. X-ray survival curves obtained *in vivo* by serial dilution assay of transplantable isologous murine tumours, after a small initial shoulder, are straight lines down to a surviving fraction of 10^{-7} (ref. 5). Survival curves reported by different workers using the Puck clonal technique would seem to conflict; some remain straight on a logarithmic-linear plot, while others bend. Before the shape of these experimentally determined curves is regarded as evidence for or against any theoretical model, it is of prime importance to ensure that all artefacts are removed from the experimental technique. Berry[5] has pointed out one such artefact which caused an apparent bending of his HeLa survival curve; failure to change medium at 7 days in plates containing a large number of cells resulted in spuriously low values of survival at high doses.

The present communication describes another artefact, which is a direct result of a basic technique in this type of *in vitro* cell survival assay. It is common practice to inoculate enough cells into irradiated plates so that approximately the same number of cells will survive to form colonies as will form on the control plates into which about 250 cells are seeded. As the dose is increased, therefore, the number of cells seeded must be rapidly increased, and it is not surprising that a point is reached where nutrient depletion and/or overcrowding would result in a spuriously low survival. When Puck and Marcus[6] first described the clonal technique they gave a warning that the low survival estimates would "necessitate such tremendous cell crowding as to require changes in the experimental technique". This advice has not always been heeded.

The following experiments were carried out to determine at what point overcrowding would seriously affect the surviving fraction. The cell line used was the HeLa $S\text{-}3_{0xf.}$ obtained from Dr. C. E. Ford at the Medical Research Council's Unit at Harwell, and recloned in this laboratory by Dr. R. J. Berry. The methods of culture followed closely those described by Puck and Marcus[6]; the medium used as a 1 : 1 mixture of *N*16 and saline *F*[7], supplemented with 15 per cent human serum. 60-mm Falcon plastic Petri dishes were used throughout. Plates to be exposed to 1,000 rads were seeded with 5×10^3 or 5×10^4 cells; plates to be exposed to 1,250 rads received 5×10^4 or 5×10^5 cells; plates to be exposed to 1,500 rads received 10^6, 5×10^5, 10^5 or 5×10^4 cells. In each experiment the medium was changed at 7 days following the advice of Berry[5]; it was found that this procedure did not affect the survival in plates containing 5×10^4 or less cells, but produced a marked effect in plates containing 5×10^5 or 10^6 cells. Surviving colonies (of more than 50 cells) were counted 14 days later, after staining and fixing. The results are plotted in Fig. 1. It is evident that changing from 5×10^3 to 5×10^4 cells per dish did not effect surviving fraction (as evidenced by the survival to 1,000 rads); however, increasing the number of cells per dish more than 5×10^4 resulted in a continuously decreasing surviving fraction (as indicated by the survival to 1,250 and 1,500 rads). Under these conditions, the survival curve shown in Fig. 2 was obtained. The number of 5×10^4 cells per plate was never exceeded; for doses more than 1,000 rads the number of plates per point was increased instead of the number of cells per plate in order that enough colonies could be counted to give a meaningful estimate of survival. Each point on the survival curve is the mean of between three and nine separate determinations.

It would seem, therefore, that after an initial shoulder, the survival curve for HeLa $S\text{-}3_{0xf.}$ cells does not depart

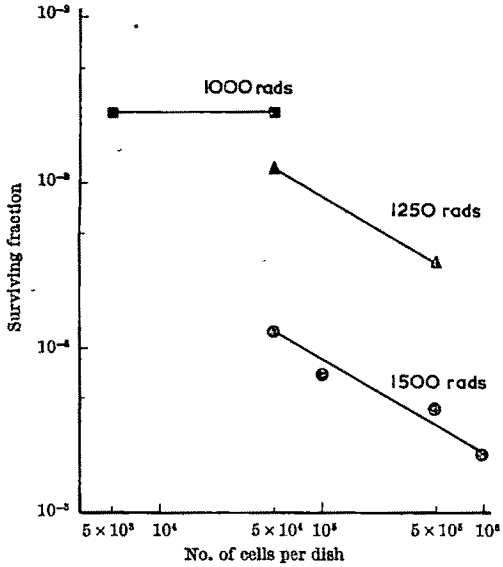

Fig. 1. Illustrating the decrease in surviving fraction that results from increasing the number of cells inoculated into each Petri dish

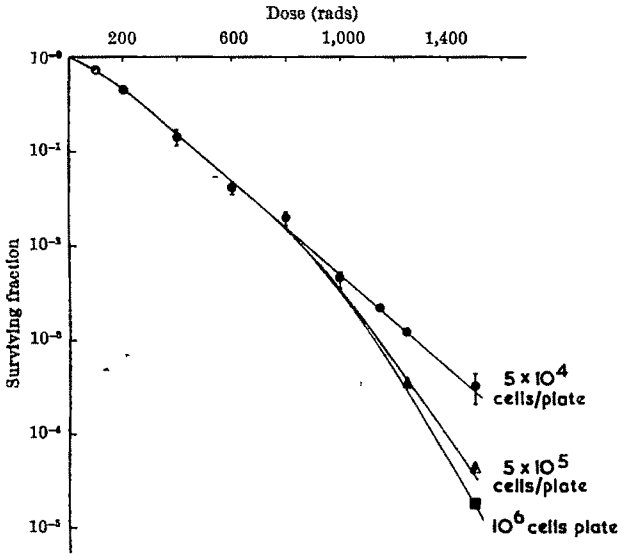

Fig. 2. Survival curve for HeLa *S*-3 *str.* cells exposed to *γ*-radiation from cobalt-60. After an initial shoulder, the curve remains straight provided that not more than 5×10^4 cells are inoculated per Petri dish. If larger numbers of cells are used, the curve continues to bend downwards

from a straight line at least down to a surviving fraction of 10^{-4}. Also plotted on Fig. 2 are the data obtained if the foregoing precaution is ignored and the number of cells per plate increased for higher doses; by this method a continuously bending curve is obtained which can be attributed to overcrowding at higher doses.

In summary, then, it must be demonstrated unequivocally that survival estimates are independent of the number of cells plated before attributing any significance to the shape of the survival curve.

BIOLOGY

Site of Action of Ribonuclease during its Inhibition of Egg Cleavage

The mitotic division of sea urchin eggs is affected by ribonuclease (RNase). Ledoux and Metz[1] found that cleavage was blocked by $1{\cdot}5 \times 10^{-4}$ M RNase, and Runnström[2] has observed that cortical changes following fertilization were delayed by RNase at one-tenth of this concentration. These effects might be expected to result from enzymatic attack of the RNA present in all parts of the egg, including the mitotic apparatus[3] and egg surface[4]. To determine which parts of the egg are affected by RNase, the site of interaction of the fluorescein-labelled enzyme with living eggs and embryonic stages of *Arbacia punctulata* and *Lytechinus variegatus* has been investigated, using fluorescence microscopy. RNase '5 X' crystalline (Nutritional Biochemicals Corp., Cleveland, Ohio) was conjugated at *p*H 9·0 with fluorescein isothiocyanate (Sylvana)[5]. Direct fluorescent labelling has been found suitable for investigating the uptake of enzymes by cells[6], and enzymatic assay and electrophoresis of fluorescein-labelled RNase showed that the fluorescein was firmly bound without destroying RNase activity[7].

Effect of RNase on cleavage. When applied at $1{\cdot}5 \times 10^{-3}$ M either 60 min before or 3 min after fertilization, RNase blocked the cleavage of at least 90 per cent of *Lytechinus* and *Arbacia* eggs, and arrested the development of the remainder at the two- or four-cell stage. The concentration required was ten times that reported[1] for a different batch of RNase from the same commercial source. The block was reduced to 75 per cent when the *p*H of the applied enzyme was adjusted from 5·1 to 7·0, and disappeared when the treated eggs were washed. Table 1 shows the delay in development resulting from different periods of treatment with $1{\cdot}5 \times 10^{-3}$ M RNase. At lower concentrations (10^{-4} to 10^{-3} M) development was delayed and the embryonic cells showed some dissociation. However, cleavage was not blocked at these concentrations, even in eggs treated after removal of their jelly coats by acidified sea-water, *p*H 4·5, and most of the eggs eventually developed into morphologically normal embryos.

To determine whether cleavage inhibition might be a general property of basic proteins, the effect of protamine sulphate on cleavage has also been investigated. At $3{\cdot}0 \times 10^{-4}$ M, protamine sulphate blocked cleavage, while the division of 50 per cent of the eggs was blocked at half this concentration. The protamine sulphate block was not reduced by adjustment to *p*H 7·0, and was only partially reversed by washing, becoming permanent after 30 min application. Since protamine sulphate also proved effective in blocking egg cleavage, inhibition of cleavage by RNase may be due primarily to its properties as a basic protein.

Site of action. When applied to living fertilized eggs at cleavage-inhibiting concentrations, fluorescein-labelled RNase (*p*H 7·2) was adsorbed on to the fertilization membrane, passed into the perivitelline space and became associated with the hyaline layer. The amount bound to the fertilization membrane and hyaline layer could be reduced by repeated washing, the reduction being constant over the *p*H range 5·0–7·0. The resolution of the technique was insufficient to permit detection of any interaction with the plasma membrane or structures associated with it, but in no case was the labelled RNase detected within the egg. When applied to unfertilized eggs, there was no interaction other than a weak surface adsorption, even after the jelly coats had been removed. During development from the blastula to the pluteus stage, labelled RNase was taken up as cytoplasmic droplets, mainly by cells of the alimentary canal. De Terra[8] has found that ferritin also becomes incorporated at the later stages of embryonic development.

Table 1. Effect of Ribonuclease ($1·5 \times 10^{-5}$ M) on the Development of *Lytechinus* Eggs

Duration of RNase treatment before washing	Delay in first cleavage (min)	Eggs developing to gastrulae Number	Per cent
None (control)	0	473/500	95
Pre-treated for 60 min before fertilization	0	469/500	94
1–30 min after fertilization	30	428/500	86
1–45 min after fertilization	90	423/500	85
Continuous after fertilization (not washed)	no cleavage	0/500	0

When fluorescein-labelled haemoglobin ($3·0 \times 10^{-4}$ M, *p*H 7·2) was applied to fertilized eggs it was bound at the same sites, suggesting that the observed binding of RNase was non-enzymatic. Treatment with fluorescein isothiocyanate at the concentration applied as the protein label (0·03 mg/ml.) showed that only the fertilization membrane was stained by unbound dye, and that the fluorescence of the hyaline layer was not an artefact due to any traces of free fluorescein. Runnström[2] also found that RNase affected the hyaline layer and fertilization membrane. The increase in birefringence[2] of the fertilization membranes of treated eggs may be partly due to the adsorption of RNase that has been observed with the fluorescent-labelled enzyme.

The reversibility of cleavage inhibition by washing and the site of interaction of fluorescent-labelled RNase with the egg both point to a post-fertilization effect on the egg surface rather than to direct interaction with any intracellular organelles. Since cleavage was blocked by similar concentrations of protamine sulphate, RNase may inhibit cleavage non-enzymatically by interacting with the egg surface as a basic protein.

Factors controlling Sexual Reproduction and Growth in *Pythium graminicola*

Recently, it was found that sterols induce the formation of oogonia in certain species of *Pythium*[1] and *Phytophthora*[2]. We have shown that the response of these organisms to sterols depends on the composition of the medium in which they are grown[3]. This communication shows that zinc and manganese as well as sterol are essential to oogonium formation in an isolate of *Pythium graminicola*; calcium seems to be required for maturation of oogonia. Zinc, manganese and sterol are also very stimulatory to the vegetative growth of this fungus.

The culture used in this study was *Pythium graminicola* Subr. isolated from soil in Hawaii. Liquid media were used throughout. Test substances, as listed in Tables 1 and 2, were added to a basal medium containing KH_2PO_4, 0·68 g; $Na_2HPO_4 \cdot 7H_2O$, 1·34 g; glucose, 15 g; KNO_3, 1·08 g; $MgSO_4 \cdot 7H_2O$, 0·25 g; distilled, de-ionized water to 1 l.

The completed media, having initial *p*H values of 6·7–6·8, were autoclaved for 15 min at 120° C, and then dispensed into Petri dishes in 18-ml. aliquots. For each medium, six plates were prepared and inoculated in the centre with agar-mycelium plugs 4 mm in diameter. After 6 or 7 days at 26° C, the mycelium from three plates was collected on separate, tared filter papers, washed, dried and weighed. After 20 or 21 days, the other three plates were examined for oogonia, and the mycelium weights were then obtained as before. In contrast to earlier investigations in which agar media were used[3], we found that oogonial formation in liquid media proceeded more slowly and appeared to be optimal only after 3 weeks of incubation. The total number of oogonia in ten fields (150×) were counted, beginning at the colony margin and at 3·5-mm intervals along a radius.

Table 1 shows the response of the fungus to iron, calcium, thiamine, cholesterol, and a trace element mixture when added singly and in all possible combinations to the basal growth medium. Both cholesterol and the trace element mixture of zinc, manganese, copper and molybdenum were required for oogonial formation. Calcium caused an increase in the number of oogonia and was essential for their maturation since, in its absence, antheridia and oospores were not observed. Thiamine was generally slightly inhibitory to oogonial formation.

The 7-day mycelial weights show that all test substances were important to vegetative growth, since the omission of any one from the complete medium led to greatly decreased growth. The order of importance of these substances was shown by factorial analysis to be trace element mixture > sterol > thiamine > calcium > iron. Numerous significant interactions appeared, all indicating additive effects on growth. The 20-day weight results were not interpreted because autolysis was evident in some cases, and suspected in others.

In order to determine the individual and interaction effects of the components of the trace element mixture, these elements were added singly and in all possible combinations to the basal medium fortified with cholesterol, thiamine, calcium and iron. Treatments and results are shown in Table 2. The media containing both zinc and manganese produced much greater oogonial counts

and 6-day mycelial weights than any of the media not containing both of these metals. The control and the manganese–molybdenum treatment are the only media which produced an appreciable number of oogonia without having both zinc and manganese present. By factorial analysis, both the latter metals were found to produce highly significant main factor effects. For vegetative growth, zinc had the greatest stimulatory effect; on interaction the effects of zinc and manganese tended to be additive. Copper and molybdenum showed no significant main factor effects. However, copper interacted significantly with the other three metals to inhibit vegetative growth, although it showed no effect on oogonial formation. As for the previous experiment, the 21-day mycelial weight results were not interpreted because of extensive autolysis.

Fothergill and Hide[5], working with four other species of *Pythium*, found that calcium, iron, trace minerals and thiamine had no effect on growth (no sterol was present). We found that all these additives stimulated the growth of *P. graminicola*, whether tested with our basal medium or with the media of Fothergill and Hide. This difference is undoubtedly attributable to a difference in the requirements of the species and isolates employed. Similarly, we found that *Pythium vexans* and *P. arrhenomanes* produced oogonia on Czapek's medium plus sterol, in the absence of zinc, manganese and calcium[3]. In addition to this, Hendrix[2] found that sterols induced sexual reproduction in *Pythium periplocum* and *Phytophthora magasperma*, although his basic medium contained no zinc, manganese or calcium. It is apparent that some species of *Pythium* have much more exacting metal ion requirements for reproduction and growth than do other species.

Protandrous Hermaphroditism in Decapod Prawns of the Families Hippolytidae and Campylonotidae

Protandrous hermaphroditism, or the changing from the male sex to the female during the growth of the same individual, is now well known in certain northern-hemisphere commercial prawns of the family Pandalidae, namely, species of the genera *Pandalus* (*P. borealis*[1], *P. danae*[1], *P. hypsinotus*[1], *P. kessleri*[2], *P. montagui*[3] and *P. platyceros*[1]) and *Pandalopsis* (*P. dispar*[1]). In the Hippolytidae, this phenomenon has been demonstrated in two European and Mediterranean species of *Lysmata*, namely, *L. seticaudata* (the first decapod in which protandry was recognized[4]) and *L. nilita*[5].

In 1959, Carlisle[6] summarized our knowledge of sex reversal in decapods, discussing the aforementioned groups and adding the burrowing axiid *Calocaris macandreae*. The latter, however, has since been shown[7] not to be a protandrous hermaphrodite, but a functional hermaphrodite throughout life. Recently I recognized protandry in the Australasian, archibenthal slope species *Campylonotus rathbunae* Schmitt and discussed the changes in secondary sexual characters involved[8]. A partially sympatric pandalid, now known as *Notopandalus magnoculus* (Bate), is not a protandrous hermaphrodite. Another species in the southern, monogeneric family Campylonotidae, the Magellanic *C. semistriatus* Bate, was also shown to be protandrous from a re-examination of the *Challenger* type material in the British Museum (Natural History).

Protandry can now be recorded in the Magellanic and Antarctic hippolytid *Chorismus antarcticus* (Pfeffer). A collection taken at Isla Navarino off the southern coast of Tierra del Fuego during the Royal Society Darwin Memorial Expedition to Southern Chile, 1958–59, consisted of males of carapace lengths 6·5–10 mm with a well-developed appendix masculina on the second pleopod, intersex specimens of 10–10·5 mm with a vestigial appendix masculina and females of 12–13 mm with no trace of this appendix.

It was also considered likely that the Indian Ocean and Australasian subantarctic hippolytid, *Nauticaris marionis* Bate, would prove to be protandrous. Preliminary examination of recent collections from Auckland and Campbell Islands in the New Zealand subantarctic, and from deep water off southern New Zealand, revealed that all the large specimens were female, mostly ovigerous, while the smaller specimens were largely male. Detailed examination, however, showed males with a well-developed appendix masculina of carapace lengths 4·5–7·5 mm, no recognizable intersex specimens and females of carapace lengths 4·5–11·5 mm. This species, then, does not show sex reversal, but mature females do reach a much larger size than males.

Protandrous hermaphroditism in decapod Crustacea appears to be restricted, so far as our knowledge goes, to two genera of northern boreal and temperate pandalids, two Mediterranean species of the hippolytid *Lysmata*, the antiboreal South American and circum-Antarctic hippolytid *Chorismus* and at least two species of the antiboreal South American and deep-water Australasian palaemonoid *Campylonotus*. The three families represented are not closely related systemically, each presently being placed in a different super-family[9], and besides the rather tenuous zoogeographic relationships (? analogous to bipolarity) no link, other than that of reproductive physiology, can be seen.

The Recent Sea-star *Platasterias* and the Fossil Somasteroidea

When discussing Fell's theories on the phylogeny of sea-stars[1–3], Philip[4] omitted any comparison of living forms with somasteroids. This comparison, however, deserves a short comment.

Spencer's sub-class of Asterozoa, the Somasteroidea[5], has always puzzled me, and I wonder whether the skeletal elements in *Villebrunaster* interpreted as ambulacralia may not be the adambulacralia, while the ambulacralia are hidden from view. I consider Spencer's virgalia to be ventrolateral ossicles. Figs. 1*a* and *b* show the resemblance between the reconstruction of a somasteroid and the ventrolateral skeleton of a recent *Porania*. (An aboral skeleton of radiate ossicles as found in some somasteroids is also present in *Porania*.) Spencer[5] compared this recent sea-star with his *Villebrunaster*, but only on account of its mucus-ciliary method of feeding which he assumed had also applied to the fossil. I would add that the resemblance stated is not taken to imply any close taxonomic relationship.

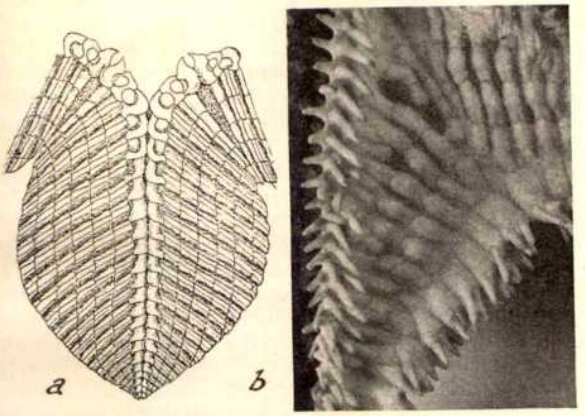

Fig. 1. *a*, *Villebrunaster* (after Spencer (ref. 5)); *b*, ventrolateral area of *Porania pulvillus* (O.F.M.)

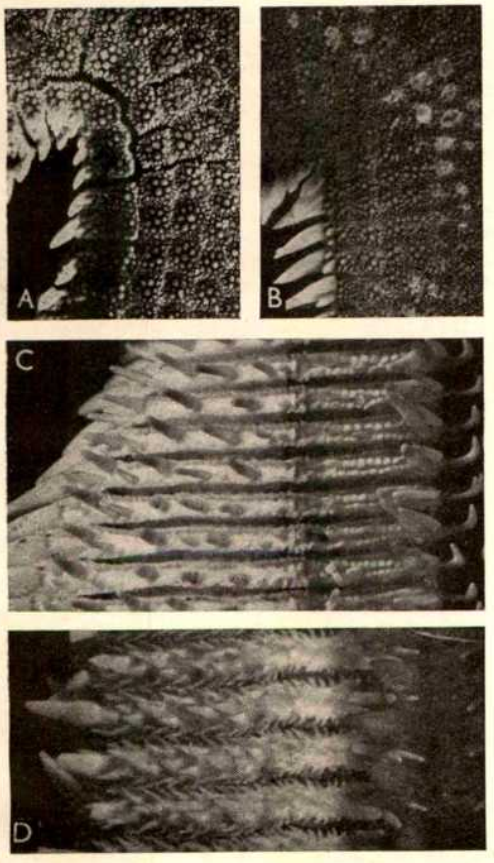

Fig. 2. Dorsal paxillae and ventrolateral skeleton of *Platasterias latiradiata* (*A*, *C*) and *Luidia* (*Petalaster*) *marginata* (*B*, *D*)

Fell[1–3] claims that *Platasterias latiradiata* Gray, 1871, is a living somasteroid. I consider this rare West-Mexican sea-star to be a somewhat aberrant *Luidia* of the sub-genus *Petalaster* (or of a sub-genus of its own). Fig. 2 illustrates the agreement in external characters between *Platasterias* and the East-Pacific *Luidia* (*Petalaster*) *marginata* Koehler. I assume the petaloid arms in *Platasterias* (brought about by a transverse elongation of the adambulacralia and inferomarginalia) to be a secondary adjustment to a life on a shifting sandy bottom (and perhaps a primarily ciliary method of feeding).

Fell[3] has put forward many interesting views on the phylogeny of sea-stars. I agree that the Luidiidae may be a very ancient group, but I fail to see how the Somasteroidea can indicate any closer affinity between asteroids and crinoids, even though *Villebrunaster* and *Chiniaster* may not be of so true an asteroid organization as I suspect.

MICROBIOLOGY

Persistence of Fluoroacetate and Fluoroacetamide in Soil

Laboratory tests have shown that sodium fluoroacetate[1,2] and fluoroacetamide[3,4] can act as systemic insecticides, and the latter compound has been tested or used in the field for pest control (mainly against aphids) in several countries[5–7]. In Britain, however, following the Smarden incident, the use of these compounds as rodenticides has been severely restricted and their use as insecticides prohibited[8].

One question that arose in an acute form from the Smarden incident was the rate of decomposition of fluoroacetamide in the soil. It also arises when the materials reach the soil from rodenticides and insecticides. According to Horiuchi[9], bacteria in the soil break down fluoroacetamide; recently the organism responsible has been isolated[10].

This communication reports results of fuller tests, of the type already described[4], to determine the persistence in the soil of both sodium fluoroacetate and fluoroacetamide. The method used was to treat moist Kettering loam and local garden soil with 10 p.p.m. and 50 p.p.m. of the compounds, which were thoroughly incorporated. The soil samples were in 1 lb. screw-top jars and, in the case of the garden soil, half the batch was steam-sterilized after the chemicals had been added at 120 lb. pressure for 2 h. This enabled a comparison to be made between the rate of breakdown in unsterilized and sterilized soil. The jars were stored at 20° C and at intervals broad beans infested with *Aphis fabae* L. were planted in the soil samples and the fate of the aphid population on each plant was followed for 5 days. Similarly infested control plants in untreated soil were also kept.

The results obtained are shown in Table 1. It can be seen that 10 p.p.m. was not detectable in the Kettering loam by this means even immediately after addition. In garden soil toxicity could be detected and lasted for 2 weeks with sodium fluoroacetate or 3 weeks with fluoroacetamide. At 50 p.p.m. a lower level of toxicity was detected by this method in the ninth week but not in the eleventh week or later. In the sterilized garden soil, at

both dosage-levels, toxicity was still evident at the end of seventeen weeks when the tests were concluded.

As an insecticide, in field tests, against aphids on beet, fluoroacetamide was used at 3 oz./acre in Britain[5]. However, it would probably be necessary to use 6 oz./acre to obtain satisfactory control of *Myzus persicae* (Sulz.). On the assumption that all this latter dose reached the upper 9–12 in. of the soil (which it would not) and remained there, this represents a concentration of 0·15 p.p.m. (taking the weight of top soil per acre to the depth indicated as 2,500,000 lb.[11]). At this concentration the compounds would not be detected by the biological method described here but, by inference, it seems safe to conclude that these small residues would also soon be destroyed.

Thus, although it may be desirable to prohibit the use of fluoroacetamide as an insecticide because of its high toxicity to mammals, the lack of a satisfactory antidote and the fact that its fate in mammals is not fully understood, there seem to be no grounds for condemning its use because of the fear that it might leave a persistent, harmful, residue in the soil. In fact, the evidence suggests that, when correctly applied as a systemic insecticide to the foliage of a field crop, any material reaching the soil would be destroyed within a few weeks, especially when the soil is warm. Of course, further tests under practical conditions and enquiries concerning the experience gained in Japan (where fluoroacetamide seems to have been fairly widely applied) would be essential before its use as an insecticide could again be contemplated.

Staphylococcal Strains with Relation to Lysostaphin Sensitivity

The sensitivity of viable *Staphylococcus aureus* (*Micrococcus pyogenes* var. *aureus*) and cell walls to the lytic action of lysostaphin has been described[1]. This communication reports experiments to determine the relative susceptibility of strains of staphylococci to lysostaph utilizing bacteriophage type and antibiotic sensitivity f strain differentiation.

It has been our experience that the rate of the decrea in turbidity of a staphylococcal suspension due to lyso staphin action varies with the different strains tested and that an extended incubation of bacterial cells with enzyme results in essentially equivalent numbers of survivors. Cropp and Harrison[2] have recently tested 252 clinical isolates of staphylococci and have compared their susceptibility to lysostaphin on the basis of the ratio of the reduction in turbidity of the test organism to that of a reference strain. Since differences in average bacterial cell size, quantity and quality of bacterial pigment, as well as released intracellular material, can all affect turbidimetric readings, experiments were designed to quantitate the number of bacterial survivors of different strains of staphylococci after a short incubation with a minima quantity of lysostaphin.

The strains of staphylococci were obtained from the Clinical Laboratory of the National Naval Medical Center, Bethesda, Maryland. Antibiotic sensitivity to penicillin (2 units), streptomycin (2 μg), tetracycline (5 μg), neomycin (30 μg), bacitracin (2 units), and kanamycin (5 μg was accomplished with 'Bacto-Sensitivity Disks' (Difco Laboratories, Detroit, Michigan) placed on agar overlays seeded with an 18-h culture of the strain under investigation.

Staphylococcal cells used in the lysostaphin susceptibility tests were from 18-h trypticase-soy broth (Baltimor Biological Laboratories, Baltimore) cultures resuspende in 0·05 M *tris*(hydroxymethyl)amino methane–hydrochloric acid buffer (*p*H 7·5) containing 0·15 M sodium chloride. Cell concentrations were adjusted to give an initial count of approximately 2×10^8 viable cells/ml. 0·2 ml. of lysostaphin (Mead Johnson Research Center Evansville, Indiana) was added to 6·0 ml. of the bacteria suspension to give a final enzyme concentration of 12 μ protein/ml. (ref. 3) (1·2 units/ml.). After 15 min a 37° C, serial dilutions of the suspension were made wit the first dilution tube containing trypsin (twice crystallized) at a concentration of 0·5 mg/ml. to stop further lysostaphin action[4]. Bacterial counts were made from pour plates after 18 h incubation. The results in Table 1 indicate that there is no definitive pattern of staphylococcal susceptibility to lysostaphin with either antibiotic sensitivity or bacteriophage type. In fact, it appears that the wide range of susceptibility to enzyme action over a short period of time is as correspondingly diverse as the bacteriophage type patterns of the different strains. Since the action of lysostaphin is directly on the bacterial cell wall mucopeptide[5] and the rate of killing cells per unit of time varies from strain to strain, it is believed that staphylococcal strain differences are directly related to cell wall composition in both the quantity and quality of the amino-acid composition of the peptide linkages. This

ould be in consort with the range of antigenicity due to ifferences of the surface mosaic and could account excluding strains that have been lysogenized) for bacteriophage susceptibility as being related to the detailed structure of the cell wall[6]. The results presented have been reproducible to ± 0·05 log, and it is conceivable that with a modification of the testing procedure to increase sensitivity and reproducibility, lysostaphin could be used to supplement bacteriophage typing and serotyping in epidemiological studies[7].

Microbiological Oxidation of Cyclic Ketones

Ali Khan, Hall and Robinson[1] have reported that when a Gram-negative bacterium (probably *Pseudomonas* sp.) was grown in an aqueous suspension of *n*-octane plus mineral salts, dioic acids (mainly suberic acid) were recovered from the medium. The activity of this bacterium (culture kindly presented by Dr. A. N. Hall) and of ten other species of bacteria on cyclic ketones has been investigated. There appears to be no previous report of microbiological oxidation of cyclic ketones. In his limited survey, Baldacci[2] could not detect any microbial activity on *cyclo*hexanone.

Ten species of bacteria which had been previously reported to oxidize hydrocarbons[3–5] were obtained from the National Collection of Industrial Bacteria and, together with the bacterium of Ali Khan *et al.*, were cultured at 30° C in an aqueous medium containing 1 per cent w/v 2-heptyl*cyclo*pentanone, plus mineral salts (0·5 per cent ammonium nitrate, 0·1 per cent magnesium sulphate, 0·02 per cent calcium chloride, 0·01 per cent ferric nitrate, and 0·1 M phosphate buffer to *p*H 7·0). After 5 days, the culture solutions were exhaustively extracted with diethyl ether after acidification, and the extracts were subjected to gas-liquid chromatography. All showed varying amounts of residual heptyl*cyclo*pentanone. The culture solutions of *Pseudomonas oleovorans* 6576, *Ps. aeruginosa* 8295, *Ps. fluorescens* 8027, *Ps. methanica* 9133 and the bacterium of Ali Khan *et al.* also contained 0·2–0·5 mg/ml. of the lactone of 5-hydroxydodecanoic acid, the first-named giving the highest yield of lactone. The lactone was identified before and after conversion to the free acid and methylation, by comparison with authentic samples of the lactone and of 5-hydroxydodecanoyl methyl ester on gas-liquid chromatographic analysis. The ethereal extracts of the culture solutions of *Ps. aeruginosa* 950 and 5940, *Ps. rubescens* 8768, *Vibrio oleo* 8250 and *Arthrobacter simplex* 8929 contained only heptyl*cyclo*pentanone. A microbiological synthesis of such lactones has been reported by Tuynenburg Muys *et al.*[6]. These authors found that the microbiological reduction of racemic keto-acids could produce optically active lactones. Therefore, the 2-heptyl*cyclo*pentanone medium of *Ps. oleovorans* was examined after culture. It was found to be laevo-rotatory. As the cyclic ketone was racemic, this activity was ascribed to the lactone. Assuming all the lactone produced was optically active, $[\alpha]_D = -36{\cdot}6°$.

It was found that *Ps. oleovorans*, *Ps. fluorescens* and the bacterium of Ali Khan *et al.* would also oxidize 2-pentyl*cyclo*pentanone, giving the lactone of 5-hydroxydecanoic acid, and would oxidize *cyclo*pentanone to glutaric acid. The last-mentioned product was identified only after methylation.

Of the total ketone initially present, less than 5 per cent was recovered as partially oxidized product, and between 60 and 70 per cent of the cyclic ketone was recovered unmodified.

Thus two or perhaps three species of bacteria, of which one is already known to promote oxidation of an *n*-alkane to dioic acids, oxidize *cyclo*pentanone to glutaric acid, a dioic acid with the same number of carbon atoms. This process involves ring cleavage, which has not been demonstrated previously with these bacteria. When asymmetric molecules of alkyl-substituted *cyclo*pentanones are offered, cleavage occurs at the most labile bond in the ring, between the two substituted carbon atoms. However, in this case, the presence of the alkyl side-chain prevents more complete oxidation to give a dioic acid. The reaction goes no further than the production of a hydroxy acid, which then lactonizes. This is further evidence to add to that of Kester and Foster[7] that microbiological oxidation of alkyl compounds to give dioic acids proceeds by way of hydroxy acid intermediates.

I thank Mr. E. Taylor for performing the polarimetry examination.

CYTOLOGY

Diffuse Centromeres in a Dicotyledonous Plant

A CYTOLOGICAL search for a sex chromosome mechanism in *Myristica fragrans*, the common nutmeg tree, has revealed some meiotic peculiarities. Mitotic metaphase counts in this admittedly unfavourable material usually gave a number of ≤4 small, more or less isodiametric elements. This is at variance with the results of Simmonds[1], who found 42 chromosomes.

At early first meiotic metaphase in a male-only flowering tree from Trinidad, I counted 22 strongly contracted chromosome bodies. These bivalents, in polar view as well as in side view, were often slightly sub-divided into two halves, thus in end view showing a quadripartite structure (Fig. 1). In late first metaphase, the configurations loosened up, mainly perpendicular to the metaphase plane, into what appeared to be four slightly interconnected chromatids. By releasing the connexions across the equatorial plane, the bivalents divided into two halves, each presumably consisting of two interconnected short chromatids, parallel to the equatorial plane. At second anaphase the chromosome bodies split into two short rods. Each attempt to localize centromeres with the help of meiotic behaviour failed. This suggested centric activity lacking localized character. Configurations really show a close similarity to those of *Luzula campestris*, as described by Brown[2].

As pointed out by Hughes-Schrader and Ris[3], induced fragments of chromosomes with such centric activity will perpetuate themselves through many cell generations. This is in contrast to the behaviour of acentric fragments of chromosomes with localized centromeres, which are

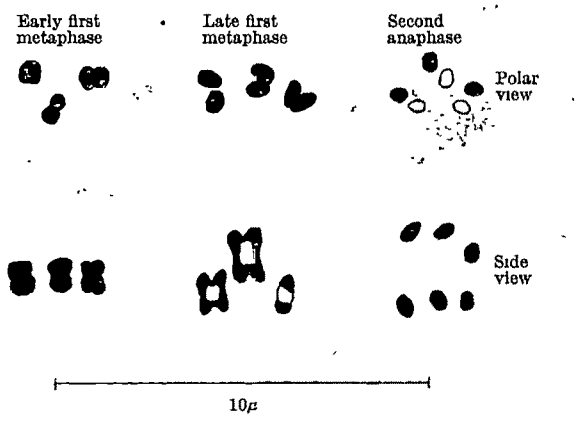

Fig. 1. Three of the 22 meiotic elements sketched with the aid of a camera lucida

rapidly lost at nuclear division. In order to verify the centromeric condition assumed, root tips irradiated with 1,000 r. were examined for fragments of chromosomes. At least one supernumerary fragment was recorded in half the metaphases counted. In preparations made at the day of irradiation and at the following day, no chromosome parts were found outside the metaphase plane of cells in full metaphase, nor any chromosome parts lagging in cells in anaphase or telophase. A second experiment (2,000 r.) did not reveal lagging fragments or micronuclei. Even 2 months after irradiation, several metaphases still showed as many as three supernumerary fragments.

These observations convince me of the presence of diffuse centromeres in the chromosomes of *Myristica fragrans*. As far as I know, this is the first report of diffuse centromeres in a dicotyledon. [Further details have been published in *Mededelingen Landbouwhogeschool, Wageningen*, 66, 1966, No. 1.]

I thank Prof. R. Prakken, Dr. J. A. Frahm-Leliveld and Dr. J. Sybenga for advice and help, Prof. J. D. Ferwerda for full use of facilities of the Department of Tropical Agriculture, and Dr. C. Broertjes of the Association Euratom-*ITAL* for irradiation. I also thank Mr. T. E. Veer and Miss van Waadenoyen Kernekamp for the elaborate microtechnical work.

AGRICULTURE

Spread of Potato Virus *Y* curtailed by Oil

Aphids continue to spread stylet-borne viruses despite present-day insecticides[1]. The finding that aphids carrying potato virus *Y* seldom transmit it after probing a surface lightly coated with oil offers a novel way of bringing this spread under control[2]. Additional laboratory work has provided various reasons for believing that oil could be used to protect crops from stylet-borne viruses[3]. We have tried this in the field for 2 years now and the results are promising.

During both years we experimented with the spread of virus *Y* in Green Mountain potatoes. In 1963 the design was a 5 × 5 Latin square, in 1964 it was an 8 × 4 randomized block; each plot was four rows wide and 30 ft. long with 33 plants per row; the plots were separated longitudinally by 25 ft. of fallow ground, and laterally by strips of oats 10 ft. wide. Spread of virus *Y* was encouraged in two ways: (*a*) a series of plots were infested with viruliferous aphids, wingless adults of *Myzus persicae* (Sulz.); (*b*) in another series each plot had twelve implanted virus *Y* infected potatoes (hereafter referred to as infectors). These grew from infected tubers planted in positions 6, 17, and 28 of each row, an arrangement that meant each infector was preceded and followed in the row by a separate group of five healthy plants. In 1963 two series of plots were infested with viruliferous aphids, and two series had infector plants. One series of each pair had oil sprayed directly on the plants six times at weekly intervals, and its counterpart was left unsprayed. The fifth series was left untreated as a check for spread between plots and from outside the trial. The 1964 trial had three additional series, all of which had infector plants. These allowed the work to be enlarged to comparisons between: (*a*) oil applied as a direct spray and oil emulsified in water, (*b*) the first three applications of each kind of spray and six applications of each, all at weekly intervals. The three series that did not receive oil in 1964 were sprayed with water on the same days and in the same way as oil was applied.

Planting was done in the middle of May with commercial seed tubers certified to be less than 0·5 per cent infected with aphid-borne viruses. All plots were sprayed with calcium arsenate soon after plant emergence and thereafter as needed to control beetles, and with Bordeaux weekly from late June until mid-August to prevent blight. To determine spread of virus *Y*, we took tuber samples at the end of August and grew them indoors during the winter. Infected plants were diagnosed from visible symptoms, with occasional checks by serological precipitin tests. In 1963 we took individual tubers from: (*a*) every plant except the infectors in plots having these, (*b*) the 200 plants infested with viruliferous aphids, and (*c*) 100 plants in each of the five check plots. In 1964 we took one tuber from each plant in the middle two rows of every plot; and to make the plot samples comparable, we discarded the tubers from the 6th, 17th, and 28th plant in each row whether they were infectors or not. We recorded the position of each tuber in the row. Of a possible 3,820 tubers from both trials, 94 plants were missing in the field and 11 tubers either failed to grow or were lost.

The oil was supplied by Imperial Oil under the designation of '862*B*' (viscosity 90–105 S.U. sec at 100° F). There is no reason to believe that this oil has any unique properties in impeding aphid transmission of stylet-borne viruses, nor was it toxic to aphids at the levels used. In both years we began spraying with oil about a week after planting, and emergence exceeded 70 per cent in all plots. In 1963 oil was applied only as a direct spray. This was done with a portable petrol-powered suction-type sprayer (model 400010 made by Solo Kleinmotoren, Stuttgart, Germany). Not knowing how much oil young potatoes can tolerate, we made the first application in 1963 with 0·5 gal./acre, and then doubled the rate each week so as concurrent tests on potatoes outside the trial showed the plants could stand the higher amounts. The successive rates of application were 0·5, 1, 2, 4, 4, and 4 gal./acre on June 19, 26, July 4, 10, 17, and 24 respectively. In 1964 the first two applications of oil were at 2 gal./acre and the remainder at twice this rate; the application dates were June 19, 26, July 2, 9, 16, and 24. For the emulsion sprays we used the same oil but with an emulsifier supplied by Imperial Oil added. The emulsion was applied with a tractor-drawn sprayer operated at a pressure of 400 lb./in.^{2}, the delivery rate being 100 gal./acre.

For viruliferous aphids we used wingless adults from a laboratory culture of *M. persicae* reared on *Brassica napus* L. They were first kept from feeding for about an hour, and then allowed to probe briefly on virus *Y* infected tobacco plants before being placed on the upper leaves of the potatoes. The plants to be infested were first thinned to a single stalk to ensure that tubers taken later for disease readings would not be from uninfested stalks. The infestation was done in both years between the

fourth and fifth applications of oil. In each of the 10 plots infested in 1963, we tagged twenty plants at random and infested each with two aphids on July 10. In 1964 we infested every plant in the middle two rows of eight plots, first with two aphids per plant on July 9 and then with one more on July 15.

In 1963 oil reduced spread by 56 per cent in plots with infectors, and by 83 per cent in those infested with viruliferous aphids. In the untreated checks 9 per cent of plants became infected; this represents the natural spread between plots and from outside the trial. Because this spread would have occurred to all plots, it is probable that it also was reduced by oil; in the series infested with viruliferous aphids and sprayed with oil, only 3 per cent of plants became infected, which is significantly less than the 9 per cent in the checks.

In 1964 there was negligible spread between plots and from outside the trial. Although few infections occurred in the infested plots, here the effect of oil was the same as in the previous year. Most of the spread in 1964 was within plots with infectors, and oil reduced it even more than in 1963. Where oil was applied directly, three applications reduced spread by 71 per cent, whereas six did so by 88 per cent. There was little difference between the effectiveness of three and six applications of emulsion —the combined effect of these two treatments being to reduce spread by 78 per cent. Thus both the direct and emulsion sprays were effective.

In the four series that had infectors and were sprayed with oil in 1964, more than half the infections were to plants immediately adjacent to infectors (Fig. 2). If the percentages in Fig 2 are converted to numbers of independent infections[4], it can be shown that the overall effect of these four oil treatments was to reduce the number of infections by 87 per cent.

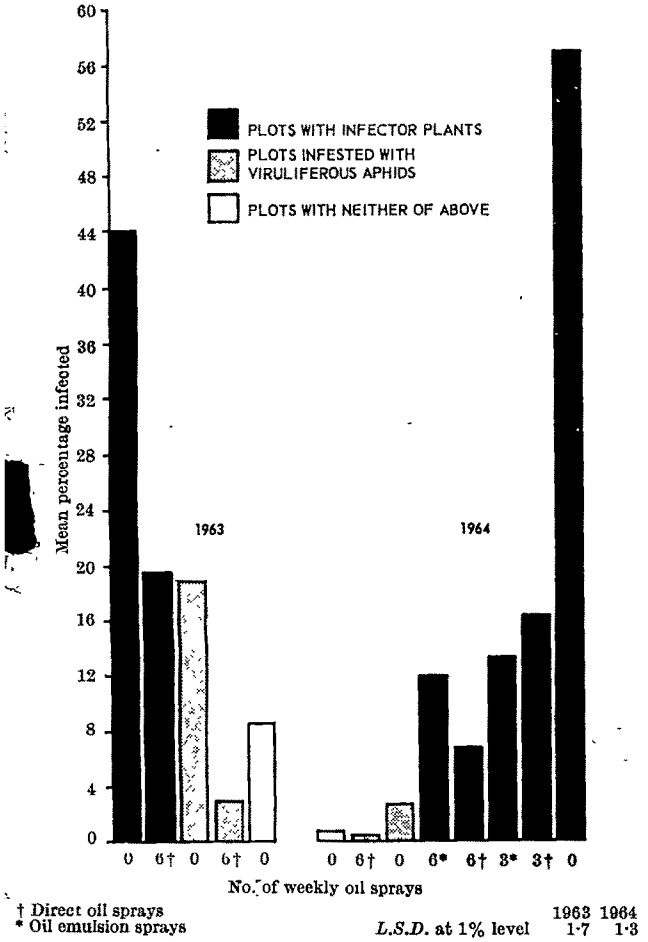

Fig. 1. Effect of oil on the spread of virus *Y* in Green Mountain potatoes during 1963 and 1964

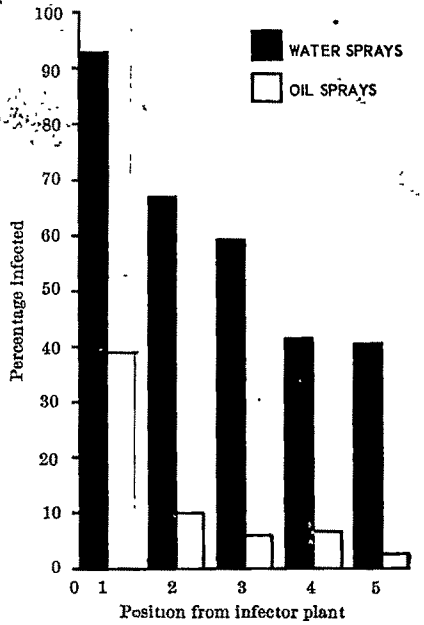

Fig. 2 Percentages of plants infected at each successive position from the infector plants in 1964—all four oil treatments were combined

Despite the rather high levels of oil applied in both years, the only visible damage to plants was some burning on occasional leaflets and petioles; direct oil sprays caused more of this than the emulsion. The oil did not reduce tuber yields in the first year; but six applications did so by about 15 per cent in 1964, although three did not affect yields.

Our results so far give us confidence that oil can be used to protect crops from virus *Y*, and there are good reasons for believing that this will also apply to other stylet-borne viruses.

PSYCHOLOGY

Differential Effects of Group Density on Social Behaviour

In a study of the social behaviour of different groups of children, one of the aspects selected for specific investigation was the effect of group density. In view of the findings from animal studies, it was hypothesized that increasing group density would have adverse effects on the nature and frequency of social encounters, and that these effects would differ according to the personality of the subject. Furthermore, if earlier hypotheses regarding the physiological activation of autistic[1,2] and brain-damaged[3] children are correct, these two groups of children might be expected to manifest, in exaggerated form, the reactions of introverted or relatively inhibited individuals and extraverted individuals, respectively, in the normal population.

The subjects of this study were fifteen children who were in- or day-patients in the hospital: five were autistic[4], five had unequivocal evidence of fairly gross brain-

damage, and five were 'normal' (that is, two normal siblings of patients and three who had recovered from minor behaviour disturbance and were about to be discharged). The last-mentioned three children did not differ significantly on any of the measures from the two who were not patients, and there seemed no *a priori* reason for not grouping all five together as 'normals'. All subjects were between the ages of 3 and 8 years, and the groups were matched for age.

The situation used for the observations was a 27 ft. × 17·5 ft. playroom where the children customarily assembled for 'free play'. Three group sizes were used: (i) small ($n \leqslant 6$); (ii) medium ($n = 7$–11); (iii) large ($n \geqslant 12$). Other children in the hospital formed the rest of the group (only two or three of the subjects were present at any one session). Groups and densities were arranged in a 3 × 3 Latin-square design, four replicates of this design then being used. An observation period per subject was 15 min and for each subject under each condition the mean of three observation periods was obtained. Observations were recorded on: (*a*) check-lists (1 entry per 10 sec); (*b*) magnetic tape; (*c*) 8-mm ciné film. Two adults, usually nurses, were always present; in the larger groups three adults were often present.

The relative proportions of time spent in aggressive or destructive behaviour (that is, fighting, snatching or breaking toys, etc.) by the three groups of subjects under the different conditions are given in Table 1.

Table 2 shows the amounts of time that were spent in social encounters with other children or adults, and which did not involve any show of aggression.

With increasing density certain children appeared to seek the safety of the boundary (that is, within 3 ft. of the periphery of the room) more frequently (Table 3).

Table 1. Mean Percentage Time (±*S.D*) spent in Aggressive/Destructive Behaviour

	Small	Medium	Large
Normal	3·0±1·7	4·6±2 4	16·1±5·2
Brain-damaged	2·7±2·8	19·0±8·2	28·0±11·2
Autist	2·5±3·7	1·9±2·8	2·1±3·4

Table 2. Mean Percentage Time (±*S D.*) spent in Social Interactions

	Small	Medium	Large
Normal	63·0±17·3	49·3±16·2	39·1±11·0
Brain-damaged	23·0±4·0	43·0±15·6	31·0±14·7
Autist	15·0±5·3	6·5±6·7	14·2±11·8

Table 3. Mean Percentage Time (±*S.D.*) spent on the Boundary

	Small	Medium	Large
Normal	15·0±6·6	13·1±4·2	10·3±5·5
Brain-damaged	24 6±3·6	8·7±4·7	16 0±4·9
Autist	21·5±7·7	30 0±9·0	55·2±6·8

Analyses of variance were carried out on the data, the appropriate error term in these cases being the 'within cells' variance, since $n > 1$. Subsequently Scheffe's test for multiple comparisons of means was applied.

For aggressive/destructive behaviour, both the main effects between groups and between densities were significant ($F = 6·8$, d.f. 2/36, $P < 0·01$, and $F = 8·3$, d.f. 2/36, $P < 0·01$, respectively), as well as the groups × densities interaction ($F = 4·2$, d.f. 4/36, $P < 0·01$). The brain-damaged subjects became more aggressive with increasing group-density, whereas the normal subjects only became significantly more aggressive in the large group. The autists showed negligible aggression.

For social encounters, there was a significant main effect between groups ($F = 22·3$, d.f. 2/36, $P < 0·01$), and a significant interaction between groups and densities ($F = 2·8$, d.f. 4/36, $P < 0·05$). The normals showed progressively and significantly less social interaction with increasing group-size. The brain-damaged subjects showed significantly more interaction in the medium group, and the autists significantly less.

For time spent on the boundary, both the main effects between groups and between densities were significant ($F = 55·8$, d.f. 2/36, $P < 0·001$, and $F = 5·4$, d.f. 2/36, $P < 0·01$, respectively), as well as the groups × density interaction ($F = 7·9$, d.f. 4/36, $P < 0·001$). As density increased, the autists spent significantly more time on the boundary.

The finding that aggressive/destructive behaviour increased in both normal and brain-damaged subjects under high densities is in agreement with other animal work: Clarke[5] found that voles in a high-density population had more numerous scars from fighting and were in poorer health than animals living in a less dense population; Chitty[6] has suggested that intraspecific strife at high population densities severely limits the number of voles, that "populations change their nature as a result of crowding, and that a change in the condition of the individuals may be reflected in the vitality of their descendants"[7]; Calhoun[8] has described the emergence of a 'behavioural sink' as well as the sexual and social deviations manifested by Norway rats reared under high-density conditions. In fact the behavioural deviations of these rats ranged from 'phrenetic' activity to 'pathological withdrawal', and it is of interest that the brain-damaged and autistic subjects tended to show predominantly these extreme reactions respectively. In a large group two brain-damaged subjects were seen to bite other children, a behaviour not manifested by any other children.

The autists, indeed, showed behaviour characteristic of physiologically highly-activated organisms: they manifested little aggression, and with increasing density retreated more and more to the periphery of the room and often would be found sitting facing the wall. Their social interactions in the large group consisted almost entirely of approaches to the adults—to escape from the general 'mêlée', it seemed.

It is remarkable that despite the greater opportunity for social interaction with the larger groups, the normal subjects in fact showed less. These subjects were apparently endeavouring to minimize their social encounters, and this is an important point in view of Calhoun's finding that the frequency and 'velocity' of social encounters in rats were markedly increased at high densities, and of Leyhausen's[9] implied suggestion that humans living in high-density conditions might show 'crowd-addiction'.

Many writers and authorities, extrapolating from the infra-primate studies, are at present warning of the social dangers of human crowding[9–12]. There is, however, a regrettable lack of empirical evidence from studies of humans in different group densities. The findings of this preliminary study would suggest that the effects of crowding are complex, and that the nature or personality of the individuals involved in the interaction is a critical variable; furthermore, it is likely that in the human species, too, certain density-dependent regulatory mechanisms are capable of operating.

A fuller analysis of the behavioural changes with different group densities is in preparation. We are grateful to the Smith, Kline and French Foundation and the British Epilepsy Association for provision of film and equipment, and to the Nuffield Foundation for financial support.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, March 28

SOCIETY OF CHEMICAL INDUSTRY, COLLOID AND SURFACE CHEMISTRY GROUP (joint meeting with the British Society of Rheology, at the School of Pharmacy, Brunswick Square, London, W.C.1), from 9.30 a.m. to 5.15 p.m. —Symposium on "Chemistry and Rheology of Water Soluble Gums and Colloids".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 10 a.m.—Colloquium on "Making Plant Models".

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Council Room of the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Mr. E. S. Clarke: "The Early History of the Nerve Cell".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (joint meeting with I.E.R.E. Television Group and the Television Society, at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m. —Mr. R. Bridgen, Mr. K. E. Martin and Mr. P. L. Mothersole: "Semiconductors in Television Receivers".

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Informal Discussion on "Caravan Towing".

PLASTICS INSTITUTE, LONDON SECTION REINFORCED PLASTICS SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. E. Millard: "The Opposition to Reinforced Plastics in the Aircraft Industry".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Mr. E. J. H. Corner, F.R.S.: "The Solomon Islands".

Tuesday, March 29

INSTITUTION OF CHEMICAL ENGINEERS, SOUTH EASTERN BRANCH (at Battersea College of Advanced Technology, Battersea Park Road, London, S.W.11), at 10 a.m.—Symposium on "High-Temperature Technology".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E.–I.E.E. COMPUTER GROUPS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 2.30 p.m. and 5 p.m.—Symposium on "Computer Control in Industry—Equipment Design and Application Engineering".

ASSOCIATION OF CLINICAL BIOCHEMISTS, SOUTHERN REGION (at the Middlesex Hospital Medical School, Cleveland Street, London, W.1), at 6 p.m. —Annual General Meeting followed by Prof. R. H. S. Thompson: "The Nervous System and the Clinical Biochemist".

INSTITUTION OF MECHANICAL ENGINEERS, RAILWAY ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Meeting on "Rubber in Coaching Stock Construction".

PLASTICS INSTITUTE, LONDON SECTION ENGINEERING SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Annual General Meeting, followed by "Basic Design Problems in Injection Moulding Equipment" (speaker from Demag AG)

Wednesday, March 30

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 3 p.m.—Meeting on "The Presentation of Navigational Information".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Dr. Alexander Comfort. "Science and Longevity" (Trueman Wood Lecture).

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at "The Crown", St. Albans Road, Garston, Herts), at 7 p.m.—Mr. A. E. Bray: "The Role of Rubber and Plastics in the Motor-Car of the Future".

Thursday, March 31

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, RADAR GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 2.30 p.m. and 5.30 p.m.—Symposium on "Monitoring of Ground and Airborne I.L.S. Equipment for Automatic Landing".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. J. S. Gillespie: "Tissue Binding of Noradrenaline" (review lecture).

INSTITUTION OF CIVIL ENGINEERS, HYDROLOGICAL GROUP (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Snowfall Measurement and the Water Balance of Ice Caps", introduced by Dr. H. Lister.

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 6 p.m.—Mr. C. H. Brissenden: "Refrigeration in the Dairy Industry".

INSTITUTION OF MECHANICAL ENGINEERS, STEAM PLANT GROUP (at 1, Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Conversion from Coal to Oil Firing".

CROYDON NATURAL HISTORY AND SCIENTIFIC SOCIETY (at Friends' Meeting House, Park Lane, Croydon, Surrey), at 7.30 p.m.—Dr. D. T. Streeter: "The Management of Nature Reserves—Some Ecological Principles".

SOCIETY OF COSMETIC CHEMISTS OF GREAT BRITAIN (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Mr. D. J. Iexander: "Some Aspects of Laboratory Planning".

Thursday, March 31—Friday, April 1

BRITISH INSTITUTE OF RADIOLOGY (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1), at 10.30 a.m. on Thursday and 10 a.m. on Friday—Twenty-Seventh Annual Congress and Exhibition.

Friday, April 1

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "Sequence Control of Plant Operations", opened by Mr. M. F. Binney, Mr. K. H. Higgens, Mr. T. K. M. Korytko and Mr. D. A. G. McInnes.

Monday, April 4

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. K. W. Pepper. "The Challenge of Synthetics to Leather".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURERS or ASSISTANT LECTURERS (2) (with a good honours degree in engineering, science or mathematics, and preferably postgraduate, industrial or research experience in one of the following fields: advanced propulsion systems, aero/space science, low density and/or high temperature gas dynamics, aircraft structures) IN THE DEPARTMENT OF AERONAUTICS AND ASTRONAUTICS—The Deputy Registrar, The University, Southampton (March 31).

LECTURER and an ASSISTANT LECTURER IN PHYSIOLOGY—The Secretary and Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (April 1).

ASSISTANT DIRECTOR (with a good honours degree in botany and experience in taxonomic work) OF THE UNIVERSITY BOTANIC GARDENS—The Registrar, The University, Liverpool, quoting Ref No. RV/482 (April 2).

LECTURER or ASSISTANT LECTURER (non-medical) IN THE DEPARTMENT OF PATHOLOGY—The Registrar, The University, Liverpool 3, quoting Ref. No. RV/476 (April 2).

SENIOR LECTURER (with high academic qualifications and the ability and desire to prosecute research) IN METALLURGY—The Principal, Lanchester College of Technology, Priory Street, Coventry (April 4).

ASSISTANT LECTURERS IN LOW TEMPERATURE PHYSICS—The Registrar, University College of North Wales, Bangor, North Wales (April 5).

HEAD OF THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Principal, Lanchester College of Technology, Priory Street, Coventry (April 5).

CHAIR OF NUMERICAL ANALYSIS—The Assistant Registrar, The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (April 6).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF ZOOLOGY—The Registrar, The University, Leicester (April 6).

CHAIR OF CHEMISTRY—The Secretary, University of Stirling, Stirling, Scotland (April 7).

LECTURER (with a higher degree such as Doctor of Philosophy and some postgraduate experience) IN ORGANIC CHEMISTRY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (April 8).

SENIOR LECTURER IN STATISTICS—The Registrar, University College of Wales, Aberystwyth (April 8).

LECTURER or ASSISTANT LECTURER (preferably with special interests in analysis or functional analysis but applications from others with interests in pure mathematics are invited) IN THE DEPARTMENT OF MATHEMATICS—The Secretary, The University, Aberdeen (April 9).

LECTURERS (2) and an ASSISTANT LECTURER (with a good honours degree in mathematics, physics or engineering and a special interest in mathematics for engineers) IN ENGINEERING MATHEMATICS—The Secretary, The University, Aberdeen (April 9).

OFFICIAL FELLOW IN PHILOSOPHY—The Principal, Brasenose College, Oxford (April 12).

UNIVERSITY DEMONSTRATOR IN ORGANIC CHEMISTRY—Dr P. Maitland, University Chemical Laboratory, Lensfield Road, Cambridge (April 12).

LECTURER IN THE DEPARTMENT OF CHEMISTRY (Inorganic and Analytical) —The Secretary, The Queen's University, Belfast, Northern Ireland (April 13).

LECTURERS or ASSISTANT LECTURERS IN THE DEPARTMENT OF CHEMISTRY —The Registrar, The University, Manchester, 13, quoting Ref. 38/66 (April 13).

LECTURER IN PURE MATHEMATICS—The Secretary, The Queen's University, Belfast, Northern Ireland (April 15).

LECTURER IN THEORETICAL PHYSICS—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (April 15).

CHAIR OF EXTRACTION METALLURGY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (April 16).

LECTURER (with a special interest in thermodynamics or mechanics of fluids) IN MECHANICAL ENGINEERING—The Registrar, The University, Sheffield (April 16).

SECOND CHAIR (candidates should have special interests in control engineering) IN THE DEPARTMENT OF ELECTRONIC AND ELECTRICAL ENGINEERING—The Registrar, The University, Sheffield (April 16).

SENIOR LECTURER IN MATHEMATICS or STATISTICS, a LECTURER or ASSISTANT LECTURER IN MATHEMATICS, a LECTURER or ASSISTANT LECTURER IN STATISTICS, a LECTURER or ASSISTANT LECTURER IN OPERATIONAL RESEARCH, and a LECTURER or ASSISTANT LECTURER IN NUMERICAL ANALYSIS—The Registrar, Bradford Institute of Technology, Bradford 7, Yorkshire (April 18).

PROFESSOR OF EDUCATION AND DIRECTOR OF THE INSTITUTE OF EDUCATION, Ahmadu Bello University, Northern Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 20).

LECTURER IN ANATOMY at Queen's College, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee (April 22).

ASSISTANT LECTURER or LECTURER IN CHEMISTRY (the appointment may be made in any branch of organic chemistry)—The Registrar, The University, Sheffield (April 30).

JUNIOR DEMONSTRATOR (preferably with experience in some branch of endocrinology, preferably steroid biochemistry) IN THE DEPARTMENT OF PHYSIOLOGY—Prof. A. A. Harper, The Department of Physiology, The Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne, 1 (April 30).

LECTURER (with interests in the theoretical and experimental aspects of modern control techniques) IN CONTROL ENGINEERING in the School of Engineering Science—The Registrar, University College of North Wales, Bangor, North Wales (April 30).

OFFICIAL FELLOW and LECTURER IN ENGINEERING—The President, Magdalen College, Oxford (April 30).

PROFESSOR OF PSYCHOLOGY—The Registrar, University Registry, Oxford (April 30).

THIRD CHAIR OF MATHEMATICS (Pure Mathematics) AT THE UNIVERSITY OF MELBOURNE, AUSTRALIA—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 1).

ASSISTANT RESEARCH FELLOW or a RESEARCH FELLOW IN SOCIOLOGY OR ANTHROPOLOGY in the East African Institute of Social Research, Makerere University College (University of East Africa), Uganda—The Inter-University Council, 33 Bedford Place, London, W.C.1 (May 2).

SENIOR FELLOWS, a SENIOR RESEARCH FELLOW, FELLOWS, and RESEARCH FELLOWS IN THE DEPARTMENT OF NUCLEAR PHYSICS, Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (May 13).

CHAIR OF VIBRATION STUDIES IN THE INSTITUTE OF SOUND AND VIBRATION RESEARCH—The Deputy Secretary, The University, Southampton (May 14).

POSTDOCTORAL RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICAL CHEMISTRY for the investigation of ion molecule reactions using a differentially pumped mass spectrometer—Dr. M. J. Henchman, Department of Physical Chemistry, The University, Leeds, 2 (May 31).

LECTURER or ASSISTANT LECTURER (graduate with an interest in yarn manufacture, including the spinning of natural and man-made fibres, and the bulking of continuous-filament yarns) IN THE DEPARTMENT OF TEXTILE TECHNOLOGY—The Registrar, The Manchester College of Science and Technology, Sackville Street, Manchester 1 (June 4).

ASSISTANT (with a good honours degree and preferably postgraduate experience) IN CELL BIOLOGY—The Secretary of the University Court, The University, Glasgow.

BIOCHEMIST (preferably experience with chromatographic and electrophoretic techniques) to join a team studying aspects of copper and magnesium metabolism in animals—The Secretary, Animal Diseases Research Association, Moredun Institute, Gilmerton, Edinburgh, 9.

LECTURER or ASSISTANT LECTURER (with a good honours degree in psychology) IN PSYCHOLOGY (Experimental Psychology/Social Psychology)—The Registrar, Goldsmiths' College (University of London), London, S.E.14.

LECTURERS or ASSISTANT LECTURERS (3) IN PURE MATHEMATICS—The Registrar, University College of Wales, Aberystwyth.

PHYSICAL CHEMIST (capable of pursuing and/or supervising basic researches mainly on electrodeposition and electroforming)—The Secretary, The British Non-Ferrous Metals Research Association, Euston Street, London, N.W.1.

PROFESSOR OF BIOLOGY—The Registrar, The Chinese University of Hong Kong, Hang Seng Bank Building, 677 Nathan Road, Kowloon, Hong Kong.

RESEARCH ASSISTANT IN HAEMATOLOGY to work on problems related to iron deficiency anaemia and tissue fibrinolytic systems—Dr. A. Jacobs, Department of Pathology, Welsh National School of Medicine (University of Wales), Royal Infirmary, Cardiff.

RESEARCH ASSISTANT (post-graduate or post-doctoral, with a good degree in botany or horticulture, but students expecting to graduate this year may also apply) for investigation of the developmental physiology of the carnation—Prof. O. V. S. Heath, F.R.S., University of Reading Horticultural Research Laboratories, Shinfield Grange, Shinfield, Reading, Berkshire.

RESEARCH ASSISTANT (with a degree in either geography or geology and a special interest in geomorphology) IN GEOLOGY—The Registrar, University College of Wales, Aberystwyth.

RESEARCH ASSISTANTS (2) IN THE DEPARTMENT OF PHYSICS to undertake (*a*) spectroscopic measurements in discharge plasmas, and (*b*) scattering measurements using lasers—The Registrar, University of York, Heslington, York.

SCIENTIFIC OFFICERS (with an honours degree in chemistry or biology and under 29 years of age) IN THE SCIENTIFIC LABORATORY for work covering a wide range of inquiry and research in the field of forensic science—The Secretary, Room 164 (SO), New Scotland Yard, London, S.W.1.

REPORTS and other PUBLICATIONS
